Aberrant light directly impairs mood and learning through melanopsin-expressing neurons

Tara A. LeGates[1]*, Cara M. Altimus[1]*, Hui Wang[2], Hey-Kyoung Lee[2], Sunggu Yang[2], Haiqing Zhao[1], Alfredo Kirkwood[2], E. Todd Weber[3] & Samer Hattar[1,2]

The daily solar cycle allows organisms to synchronize their circadian rhythms and sleep–wake cycles to the correct temporal niche[1]. Changes in day-length, shift-work, and transmeridian travel lead to mood alterations and cognitive function deficits[2]. Sleep deprivation and circadian disruption underlie mood and cognitive disorders associated with irregular light schedules[2]. Whether irregular light schedules directly affect mood and cognitive functions in the context of normal sleep and circadian rhythms remains unclear. Here we show, using an aberrant light cycle that neither changes the amount and architecture of sleep nor causes changes in the circadian timing system, that light directly regulates mood-related behaviours and cognitive functions in mice. Animals exposed to the aberrant light cycle maintain daily corticosterone rhythms, but the overall levels of corticosterone are increased. Despite normal circadian and sleep structures, these animals show increased depression-like behaviours and impaired hippocampal long-term potentiation and learning. Administration of the antidepressant drugs fluoxetine or desipramine restores learning in mice exposed to the aberrant light cycle, suggesting that the mood deficit precedes the learning impairments. To determine the retinal circuits underlying this impairment of mood and learning, we examined the behavioural consequences of this light cycle in animals that lack intrinsically photosensitive retinal ganglion cells. In these animals, the aberrant light cycle does not impair mood and learning, despite the presence of the conventional retinal ganglion cells and the ability of these animals to detect light for image formation. These findings demonstrate the ability of light to influence cognitive and mood functions directly through intrinsically photosensitive retinal ganglion cells.

In mammals, all light information for image formation and regulation of behaviour is detected by the retina and signalled to the relevant brain targets through retinal ganglion cells (RGCs). Most RGCs signal light to thalamic relay nuclei and then to the visual cortex for image functions. A population of intrinsically photosensitive RGCs (ipRGCs[3,4]), which predominantly signal light information for non-image-forming visual functions, expresses the photopigment melanopsin and can be distinguished from most RGCs that support image tracking and detection[5]. ipRGCs project to several hypothalamic and preoptic areas such as the suprachiasmatic nucleus (SCN), subparaventricular nucleus and ventrolateral preoptic area to regulate circadian rhythms and sleep. However, they also project to limbic regions such as the lateral habenula and the medial amygdala[4,6], highlighting a possible role in the regulation of cognitive functions.

To determine how aberrant light influences behaviour, we subjected mice to an ultradian cycle consisting of 3.5-h light and 3.5-h dark (T7). Our previous studies showed that this T7 aberrant light cycle does not affect the architecture (Supplementary Fig. 1) or the total sleep levels when compared to a 12 h:12 h light–dark (T24) control cycle[7]. We also determined whether the circadian timing system was disrupted in the T7 animals by measuring core body temperature and general activity rhythms. The T7 cycle does not cause circadian arrhythmicity in either output rhythm (Fig. 1a, b and Supplementary Fig. 2), although the circadian period is lengthened.

To determine whether the T7 cycle influences the molecular basis of the circadian clock, we measured circadian changes of a molecular clock component (PER2) in central (SCN) and peripheral (liver) tissues. Mice housed in the T7 cycle show similar rhythms and localization of PER2 expression in the SCN as in littermates housed in the T24 cycle (Fig. 1c and Supplementary Fig. 3), indicating no disruption of internal rhythmicity of the SCN pacemaker. Furthermore, *Per2* levels in the liver from mice housed in the T24 or T7 light cycle were intact and showed similar phases (Fig. 1d). Together, these data show that the T7 light cycle does not disrupt sleep or cause circadian arrhythmicity. Although the circadian timing system and sleep remain intact under the T7 light cycle, mice are exposed to light pulses at all circadian phases during the experimental time course owing to the mismatch between the imposed light cycle and the period length. Thus, the T7 cycle will allow us to determine the direct influence of aberrant light exposure on mood and cognitive functions.

The T7 model causes light to appear during the night (active) phase of the animals' cycle. To determine which brain regions respond to light presented at night, we measured expression of the transcription factor c-Fos in response to an acute light pulse. After examination of ipRGC targets that are part of or known to influence the limbic system, we found light-induced c-Fos expression in the amygdala, lateral habenula and subparaventricular nucleus (Supplementary Fig. 4). This suggests that light input particularly when presented at an aberrant time of day may influence regions of the brain involved in mood and cognitive functions.

Shorter day-length during the winter months leads to a seasonal form of depression known as seasonal affective disorder (SAD), and appropriately timed light therapy can alleviate the symptoms of SAD[8]. We thus investigated whether the T7 cycle, which exposes animals to light at inappropriate times, causes depression-like behaviours in mice by evaluating sucrose anhedonia and behavioural despair in the forced swim test (FST). Mice housed in the T7 cycle showed decreased sucrose preference, indicating an increase in depression-like behaviour (Fig. 1e and Supplementary Fig. 5). This was further supported by the FST; mice housed in the T7 cycle spent significantly more time immobile than mice housed in the T24 cycle (Fig. 1f).

An established association with depression is increased serum corticosterone levels[9]. We measured serum corticosterone in animals housed in T24 or T7 cycles at four time points across the day. Although we found an intact circadian rhythm in corticosterone with a similar phase to mice housed in the T24 cycle, the overall levels of corticosterone were increased in mice housed in the T7 light cycle (Fig. 1g).

Increases in corticosterone levels as well as anhedonia are correlated with increased stress and anxiety[10]. To assay anxiety-like behaviour, we

Scale bars, 200 μm. **d**, Liver *Per2* expression was rhythmic ($P_{time} = 0.0072$) ($n = 3$–4 per time point, $P_{light\ cycle} = 0.8482$). CT, circadian time; ZT, zeitgeber time. **e**, T7 mice showed sucrose anhedonia ($n = 16$ (T24) and $n = 15$ (T7), $P < 0.0001$). **f**, T7 mice showed increased immobility in the FST ($n = 22$ per group, $P = 0.0002$). **g**, Corticosterone levels were rhythmic but increased in T7 mice ($n = 5$–6 per time point, $P_{time} < 0.0001$, $P_{light\ cycle} < 0.0001$, Bonferroni post-test: $P < 0.05$ ZT/CT 1 and $P < 0.01$ ZT/CT 13). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$; $^{****}P < 0.0001$. Error bars indicate s.e.m.

used three tests: open field test, light–dark box and elevated plus maze. We found no significant difference between animals maintained in the T24 cycle and those in the T7 cycle (Supplementary Fig. 6). These results show that the T7 cycle does not globally influence behaviour but specifically elicits depression- and not anxiety-like behaviours.

Increased serum corticosterone levels and depression have been closely associated with hippocampal learning deficits[11]. We conducted a hippocampal-dependent task, the Morris water maze (MWM) (Fig. 2a–d). In the MWM, the T7 mice required significantly more trials to achieve the same latency in locating a hidden platform compared with the T24 mice (Fig. 2b), despite similar swim speeds. All our measurements were done during the day in the T24 mice (Supplementary Fig. 7). Previous studies using the MWM have shown that mice use a hippocampal-dependent spatial strategy and a hippocampal-independent non-spatial strategy to locate the platform[12]. We sought to determine whether the deficit in learning acquisition in the T7 mice was due to the lack of hippocampal-dependent spatial learning. We therefore conducted a probe trial, in which the platform in the water maze was removed from the target quadrant[13] (Fig. 2c). We found that mice housed in the T24 cycle showed a significant preference for the target quadrant, whereas mice housed in the T7 cycle showed no preference for the target quadrant (Fig. 2c). Using a reversal assay, mice housed in the T24 cycle required significantly more trials to locate the platform in the new quadrant, whereas the T7 mice showed no change in the latency to locate the platform (Fig. 2d). This further supports the dependence of T7 mice on a non-spatial escape strategy, highlighting a hippocampal- dependent learning deficit.

Spatial learning deficits are usually associated with long-term potentiation (LTP)[14] decrement in the hippocampus. We found that mice housed in both the T24 and T7 cycles have similar basal synaptic transmission at the Schaffer collaterals in the hippocampus (Fig. 2e, f). However, mice housed in a T7 cycle showed impaired LTP in response to both one and four pulses of theta burst stimulation (TBS; Fig. 2g, h). We found no difference in low-frequency stimulation-induced long-term depression (LTD) between mice housed in the T24 and T7 cycles (Fig. 2i). Impaired LTP with no change in LTD has been previously associated with sleep deprivation[15]. The selective LTP deficits observed in mice housed in the T7 aberrant light cycle independent of sleep deprivation indicates that learning impairments due to inappropriate light exposure and sleep deprivation may use similar neural pathways (see model in Supplementary Fig. 13).

To determine whether the learning deficits in the T7 cycle extend to tasks involved in hippocampal-dependent recognition memory, we conducted the novel object recognition test[16]. Mice housed in the T24 cycle showed a significant preference for the novel object (Fig. 2j). By contrast, mice housed in the T7 cycle showed no preference for a novel object from a familiar object (Fig. 2j).

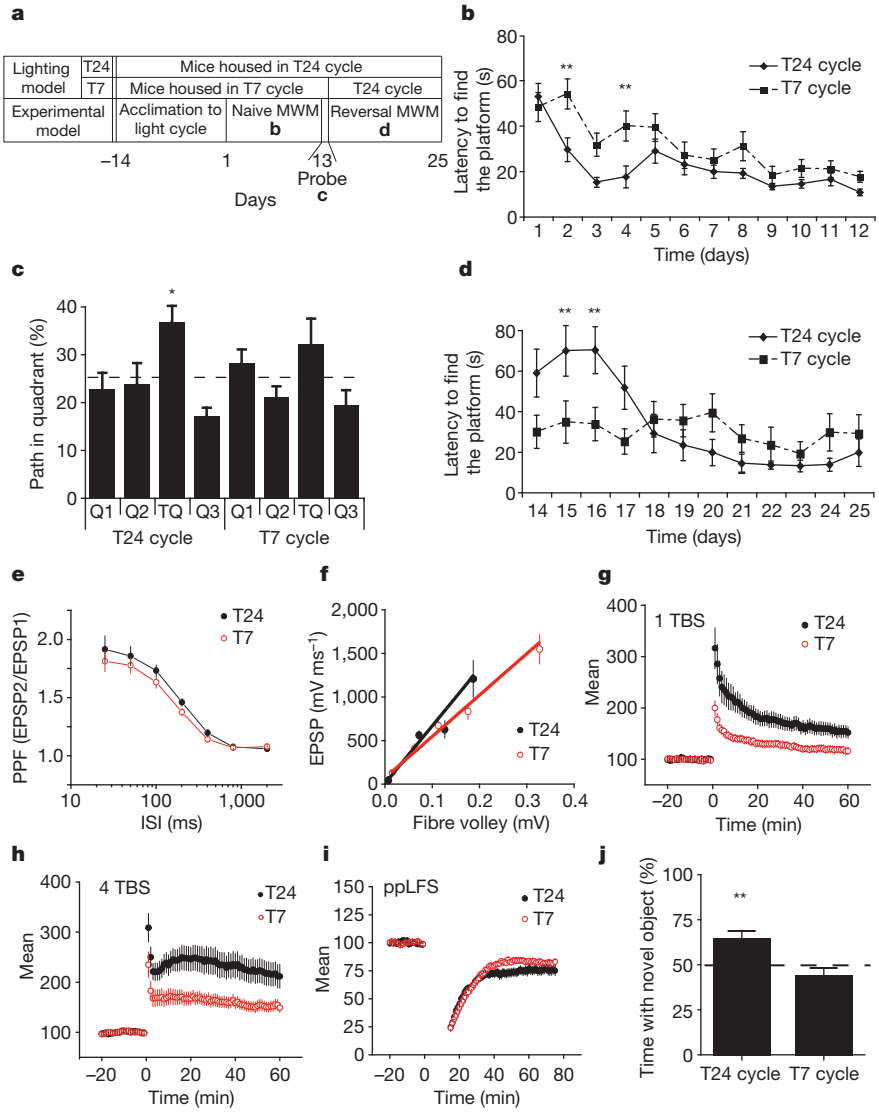

Figure 2 | Aberrant light impairs hippocampal learning, LTP, and recognition memory. **a**, Experimental model for the MWM. **b**, T7 mice showed impaired learning ($n = 21$ per group, $P_{interaction} = 0.041$, Bonferroni post-test $P < 0.01$ days 2 and 4). **c**, T7 mice show no significant preference for the target quadrant (TQ) (T24: $n = 9$, $P = 0.011$; T7: $n = 9$, $P = 0.25$). Dotted line indicates chance (25%). **d**, Mice housed in the T24 cycle showed an increased latency in a reversal trial, whereas T7-housed mice show a similar latency to the acqusition phase ($n = 9$ per group, $P_{interaction} < 0.0003$, Bonferroni post-test: $P < 0.01$ days 15 and 16). **e**, **f**, T24 and T7 mice have similar basal synaptic release properties ($P_{interaction} = 0.7256$) ($n = 5$ per group) (fibre volley: $P_{interaction} = 0.984$, slope: $P > 0.1$). EPSP; excitatory postsynaptic potential; ISI, interstimulus intervals; PPF, paired-pulse facilitation. **g**–**i**, T7 mice showed LTP deficits ($n = 5$ per group, 1 TBS: $P_{interaction} < 0.01$; 4 TBS: $P_{interaction} < 0.01$) (**g** and **h**) but no difference in LTD (**i**). ppLFS, paired-pulse low-frequency stimulation. **j**, T7 mice showed deficit in novel object recognition (T24: $n = 24$, $P = 0.0057$; T7: $n = 24$, $P = 0.1773$). $^*P < 0.05$; $^{**}P < 0.01$. Error bars indicate s.e.m.

To investigate whether antidepressants could rescue the learning deficits observed in T7 mice, we chronically administered fluoxetine to T24 and T7 mice (Fig. 3a). Chronic fluoxetine treatment decreased depression-like behaviour in mice housed in the T7 cycle (Fig. 3b). Furthermore, this treatment was able to rescue the learning deficit observed in the novel object recognition test (Fig. 3c). In support of this behavioural rescue of hippocampal function, chronic fluoxetine treatment also rescued the LTP deficit induced by the T7 cycle (Fig. 3d). Subchronic fluoxetine treatment did not rescue the increased depression or learning defect observed in mice housed in the T7 cycle (Supplementary Fig. 8), consistent with published reports[17]. We also used desipramine, a tricyclic antidepressant, and found that desipramine restored learning (Supplementary Fig. 9 and Supplementary Information). These results show that the detrimental behavioural changes induced by aberrant light exposure can be alleviated with antidepressant administration.

To determine the mechanism by which fluoxetine restores learning, we measured the circadian period in T7 mice treated with fluoxetine. Although fluoxetine can phase shift the circadian oscillator[18], chronic administration of fluoxetine did not change the length of the circadian period in mice housed in the T7 cycle (Supplementary Fig. 10). We then examined the corticosterone rhythms in fluoxetine-treated T7 mice and showed that corticosterone rhythms persist with lower overall levels compared with untreated mice (Fig. 3e). These data indicate that fluoxetine treatment does not alter circadian rhythms but instead lowers the level of corticosterone, which could lead to lower depression-like behaviour and better learning.

Studies have suggested that ipRGCs, in addition to affecting reflexive, irradiance-dependent non-image forming visual functions, might directly influence higher cognitive functions and brain processing of emotions[19–22]. To determine directly whether ipRGCs mediate the effects of the T7 cycle on mood and learning, we tested mice lacking ipRGCs (*Opn4*$^{aDTA/aDTA}$, herein referred to as aDTA mice). Although most ipRGCs are ablated, these mice still retain more than 95% of RGCs and are capable of image formation[5]. First, we compared wild

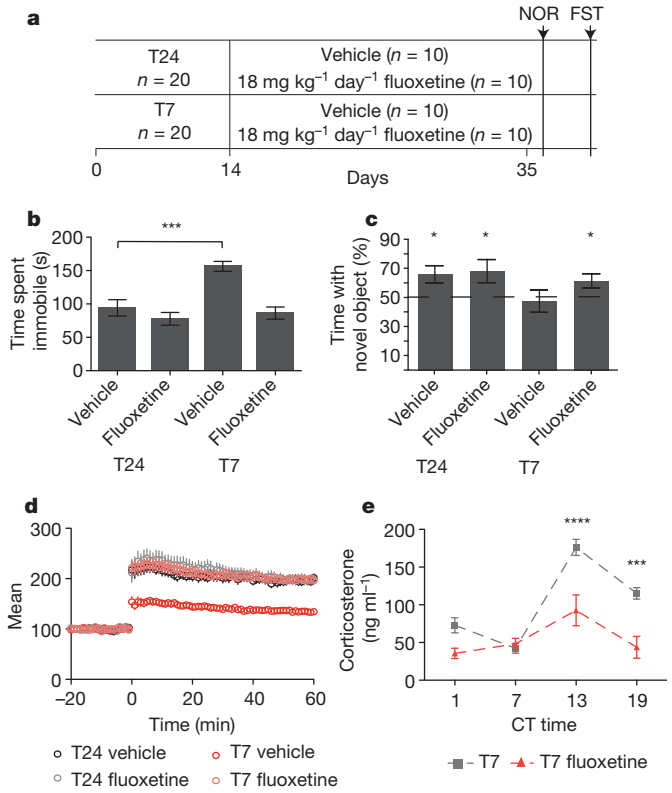

Figure 3 | Chronic antidepressant administration rescues learning. **a**, Timeline for fluoxetine administration and testing. NOR, novel object recognition. **b**, Chronic fluoxetine reduced T7 immobility time in the FST ($n = 10$ per group, $P_{interaction} = 0.0092$, Bonferoni post-test: $P < 0.001$ T24 versus T7 vehicle). **c**, T7 mice treated with fluoxetine showed restored novel object preference ($T24_{vehicle}$: $n = 9$, $P = 0.03$; $T24_{fluoxetine}$: $n = 9$, $P = 0.048$; $T7_{vehicle}$: $n = 10$, $P = 0.77$; $T7_{fluoxetine}$: $n = 10$, $P = 0.04$). **d**, Chronic fluoxetine rescued the T7-induced LTP deficit ($n = 5$ (T24 vehicle), $n = 5$ (T24 fluoxetine), $n = 5$ (T7 vehicle), and $n = 4$ (T7 fluoxetine); $P_{interaction} < 0.0001$). **e**, Chronic fluoxetine decreased corticosterone levels in T7 mice ($n = 5$–8 per time point). T7 corticosterone levels are plotted for comparison. ($P_{interaction} = 0.0053$, Bonferroni post-test: $P < 0.0001$ CT 13 and $P < 0.001$ CT 19.) $^*P < 0.05$; $^{***}P < 0.001$; $^{****}P < 0.0001$. Error bars indicate s.e.m.

type to aDTA littermates and showed no differences in baseline for the FST and corticosterone levels (Supplementary Fig. 11). We then placed aDTA mice under T24 and T7 cycles and found no difference in anxiety-like behaviours between the two groups (Supplementary Fig. 12). By contrast, the increased depression-like behaviour, learning deficits and hippocampal LTP decrement observed in the T7 cycle in wild-type animals were not observed in aDTA mice exposed to this cycle (Fig. 4). These results indicate that the negative influence of the aberrant light cycles on behaviour requires ipRGCs. Thus, subconscious light detection in humans via ipRGCs may be responsible for the depression and learning deficits observed under disruptive light environments.

Manipulation of the light environment can lead to disruptions in circadian rhythms and sleep and also cause mood and learning defects in mice and humans[2,23,24]. These studies have led to a model in which light affects cognition exclusively through the modulation of sleep and circadian pathways (Supplementary Fig. 13). Here, we provide a further model in which light directly influences mood leading to learning deficits in the context of an intact circadian timing system and normal sleep distribution and architecture (Supplementary Fig. 13a). Further support that the effects of the T7 cycle are not due to circadian disruptions originate from behavioural comparisons to animals lacking a functional circadian oscillator (for example, circadian mutant- or SCN lesioned- animals), in which reduced depression-like behaviour is observed[25,26] (Supplementary Fig. 13b). Taken together,

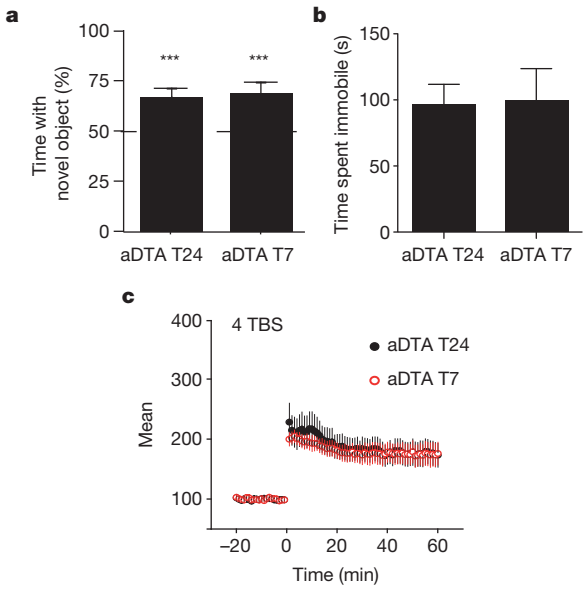

Figure 4 | ipRGCs mediate impairment of mood and learning by aberrant light. **a**, Mice lacking ipRGCs showed a significant preference for the novel object when housed in both the T24 and T7 light cycles ($n = 12$ per group, $P < 0.001$). **b**, aDTA mice housed in the T7 cycle performed similarly to those housed in the T24 cycle in the FST ($n = 6$ (T24) and $n = 5$ (T7), unpaired t-test: $P = 0.93$). **c**, T7 aDTA mice had similar LTP to T24 aDTA mice in response to four-pulse TBS. $^{***}P < 0.001$. Error bars indicate s.e.m.

these data provide evidence that the aberrant light effects on mood are direct. Furthermore, the depression-like behaviour caused by the T7 aberrant light cycle can serve as an alternative experimental model for depression research in rodents, independent of genetic manipulations or aversive treatments such as repetitive restraint or electric shocks.

METHODS SUMMARY

Adult (4–8 months) male mice (B6/129 F_1 hybrid; Jackson Laboratory) were used for all experiments involving wild-type mice placed under different light environments. Adult littermate aDTA mice placed under different light environments were of B6/129 background (6–8 months) and were raised in our laboratory. aDTA mice could not be used until they were at least 6 months old because elimination of the melanopsin cell population in these mice is not complete until this time[5]. All mice were individually housed in standard animal facility cages with access to food and water *ad libitum*. All mice were initially entrained to a 12 h:12 h light–dark cycle (T24), after which the lights for one group were switched to a 3.5 h:3.5 h light–dark cycle (T7) for 2 weeks. The light intensity during the light portion was ~800 lx, chosen to cause no circadian arrhythmicity. All experiments were done in accordance with the regulations set forth by Johns Hopkins University and Rider University Animal care and use committee.

Behavioural analysis. Mice were maintained in the T24 or T7 light cycle for 2 weeks before testing unless otherwise indicated. Body temperature and general activity were measured to evaluate circadian rhythmicity. Sucrose preference and the FST were used to assess depression-like behaviour. The MWM and novel object recognition test were used to assess hippocampal-dependent learning.

Cellular and molecular analysis. To examine the circadian timing system, immunohistochemistry and qRT–PCR were used to quantify PER2 expression in the SCN and liver, respectively. Serum corticosterone levels were quantified by ELISA. Electrophysiological recordings from the dorsal hippocampus were performed to evaluate hippocampal function including LTP and LTD.

METHODS

Animals and housing. Adult (4–8 months) male mice (B6/129 F_1 hybrid; Jackson Laboratory) were used for all experiments involving wild-type mice placed under different light environments. Adult littermate aDTA mice placed under different light environment were of B6/129 background (6–8 months) and were raised in our laboratory. aDTA mice could not be used until they were at least 6 months old because elimination of the melanopsin cell population in these mice is not complete until this time[5]. All mice were individually housed in standard animal facility cages with access to food and water *ad libitum*. All mice were initially entrained to a 12 h:12 h light–dark cycle (T24), after which the lights for one group were switched to 3.5 h:3.5 h light–dark (T7) for 2 weeks. The light intensity during the light portion was ~800 lx, chosen to have no circadian arrhythmicity. All experiments were done in accordance with the regulations set forth by Johns Hopkins University and Rider University Animal care and use committee.

Body temperature measurements. Body temperature measurements were made using G2 E-mitter telemetric probes from Mini Mitter (Respironics). The telemetric probe was implanted into the peritoneum and sutured to the inside of the abdominal wall. Mice were given 1 week to recover from surgery before any recording.

Recordings were obtained using Vitalview software (Respironics), at a rate of 30 measurements per hour. Throughout, experiment mice were maintained in their home cage without perturbation and the light cycles were adjusted to test response to both the T24 and T7 light cycles. Circadian period was determined by fitting a regression line to the onsets of activity over a 7-day period using Clocklab (Actimetrics). Period lengths of mice housed in the T24 and T7 light cycles were compared using an unpaired Student's *t*-test.

General activity measurements. General activity was measured using infrared motion detectors from Mini Mitter (Respironics). Mice were housed individually, and the motion detector was mounted to the top of the cage so that general activity could be monitored throughout the T24 and T7 light cycle. Data were collected in 10-min bins using Vitalview software (Respironics). Circadian period length was determined by fitting a regression line to the onsets of activity over a 7-day period using Clocklab (Actimetrics). Period lengths of mice housed in the T24 and T7 light cycles were compared using an unpaired Student's *t*-test.

Molecular rhythm measurements. Mice were housed in either the T24 ($n = 16$) or the T7 ($n = 16$) light cycle for 2 weeks, during which general activity was monitored in T7 mice to determine their circadian phase. Mice were sampled across four time points. Mice under the T24 cycle were sampled at ZT 1, 7, 13 and 19, and mice under the T7 cycle were sampled at CT 1, 7, 13 and 19, which was determined using their general activity rhythm. Each mouse was removed from its cage, and tail blood was quickly sampled. The mouse was then anaesthetized with 1 ml of avertin (20 mg ml^{-1}). Once anaesthetized, a small sample of liver was isolated. The mouse was then perfused transcardially with 0.9% saline followed by 4% paraformaldehyde. The brain was removed and postfixed overnight in 4% paraformaldehyde followed by cryoprotection and embedding in OCT compound (Sakura Finetek).

Real-time PCR. Liver samples were homogenized and RNA extracted using the RNeasy mini kit (Qiagen). The Retroscript kit (Ambion) was used to reverse transcribe poly(A) RNAs. Real-time quantitative PCR was performed with iQ SYBR Green Supermix and the iCycler iQ real-time PCR detection system (Bio-Rad). Each sample was analysed in triplicate reactions of 50 µl. Primers for *Per2* were forward: 5′-GCCTTCAGACTCATGATGACAGA-3′ and reverse: 5′-TTTGTGTGCGTCAGCTTTGG-3′. Primers for 18S rRNA (internal control) were forward: 5′-CGCCGCTAGAGGTGAAATTC-3′ and reverse: 5′-TTGGCAAATGCTTTCGCTC-3′.

Data were analysed using the $\Delta\Delta C_t$ method, normalizing each sample to the internal control, and relative messenger RNA was determined as the percentage of the maximum value observed in the experiment. Data were analysed by two-way analysis of variance (ANOVA) followed by a Bonferroni post-hoc test to examine differences over time as well as potential light cycle effects on *Per2* expression.

PER2 immunohistochemistry. Brains were sectioned (40 µm) by cryostat through the rostral–caudal extent of the SCN, and were stored free floating in 0.1 M phosphate buffer. Free-floating sections were incubate in blocking buffer (0.1 M phosphate buffer, 3% triton, 0.5% bovine serum albumin and 1% goat serum) for 2 h. Sections were then incubated in rabbit anti-Per2 (Alpha Diagnostic International; 1:4,000 in blocking buffer) overnight and visualized with a Vectastain horseradish peroxidase kit (Vector Labs) using 3,3′-diaminobenzidine (DAB; Sigma). Sections were mounted on microscope slides, dehydrated and coverslipped with Permount. Sections were imaged at ×10 magnification with a Zeiss Axio Imager M1 microcsope. Optical density was measured using ImageJ. Data were analysed by two-way ANOVA followed by a Bonferroni post-hoc test to examine differences over time as well as potential light cycle effects on PER2 expression.

Corticosterone measurement. Serum was isolated from collected tail blood and assayed for corticosterone by ELISA (Assaypro). Data were analysed by two-way ANOVA followed by a Bonferroni post-hoc test to examine differences over time as well as light cycle effects on corticosterone levels. For fluoxetine experiments, corticosterone levels were analysed by two-way ANOVA followed by a Bonferroni post-hoc to examine differences over time as well as the effect of fluoxetine.

For the experiment comparing wild-type and aDTA mice, serum was sampled from wild-type and aDTA mice at ZT 13/CT 13 based on general activity rhythms (as described above). The samples were processed as described above. Corticosterone levels of wild-type and aDTA mice were analysed by unpaired Student's *t*-test.

Light-induced c-Fos expression. Mice were housed under a 12 h:12 h light–dark cycle and were exposed to a 10-min light pulse at ZT 14 (2 h after light offset), after which they were placed back in the dark for a further 80 min. Control mice remained in the dark until anaesthetization. Ninety minutes after the start of light presentation, mice were deeply anaesthetized with 1 ml of avertin (20 mg ml^{-1}). Once anaesthetized, the mice were perfused transcardially with 0.9% saline followed by 4% paraformaldehyde. Brains were removed, postfixed overnight in 4% paraformaldehyde, and then transferred to 0.1 M phosphate buffer. Brains were sectioned (40 µm) through the rostro–caudal extent of the SCN using a vibrotome (World Precision Instruments). Sections were stored free floating in 0.1 M phosphate buffer. Every other section was stained immunohistochemically for c-Fos. Sections were incubated in blocking buffer (0.1 M phosphate buffer, 3% Triton X-100 and 0.5% bovine serum albumin) for 2 h. Sections were incubated in rabbit anti-c-Fos (Calbiochem Ab-5; 1:20,000) overnight at 4 °C and then visualized with a goat anti-rabbit Vectastain horseradish peroxidase kit (Vector Labs) using DAB (Sigma) as a chromagen. Sections were mounted on microscope slides, dehydrated and coverslipped with Permount. Slides were viewed and imaged on a Zeiss Axio Imager.M1 microscope at ×5 magnification. Photoshop and ImageJ were used to count c-Fos-positive cells and measure the area of region counted from. The number of c-Fos positive cells was normalized to the area of the region, and these values were compared between mice that received a light pulse and dark controls. These data were analysed using an unpaired Student's *t*-test.

Sucrose anhedonia. Mice were housed in the presence of two water bottles 1 day before testing to acclimate them to the bottles. Sucrose preference was assessed over 2 days. Each day, one bottle containing 1% sucrose and one bottle containing water were introduced at the beginning of the active phase. The position of these bottles was switched 6 h later, and the bottles were removed at the end of the active phase. Bottles were weighed at the beginning and end of the active period to measure amount consumed. Sucrose preference was calculated by dividing the amount of sucrose consumed by the total amount consumed (water and sucrose). The percentage of sucrose consumed by mice in the T24 and T7 cycles was compared by a Student's *t*-test.

FST. Mice were individually placed in an inescapable container of water (25 °C) for 6 min. Behaviour was monitored by video cameras positioned in front of the apparatus and scored by a video tracking system (Forced Swim Test, Bioserve). Time spent immobile for the last 4 min of the test was calculated. Increased time spent immobile is indicative of increased depression-related behaviour. The amount of time spent immobile during the last 4 min was analysed by Student's *t*-test. For fluoxetine experiments, the amount of time spent immobile during the last 4 min were analysed by two-way ANOVA followed by a Bonferroni post-hoc to compare light cycle and drug treatment.

Open field. Mice were individually placed in the centre of a large, brightly lit arena (500 lx, 60 × 60 cm) and allowed to explore for 5 min. Behaviour was monitored from above by a video camera connected to a computerized video tracking system (Anymaze, Stoelting). The apparatus was cleaned thoroughly between each trial. The percentage distance travelled and time in the centre of the arena were measured. These measures were compared between mice housed in the T24 and T7 cycles using an unpaired Student's *t*-test.

Light–dark box. The light–dark box consisted of two compartments equivalent in size (20 × 20 cm); one area is brightly lit (600 lx) and the other is dimly lit (<1 lx). A small opening joins the two compartments, so the mice could freely move between the two areas. Mice were dark adapted for 1 h before testing. At the beginning of the test, dark-adapted mice were placed in the lit compartment facing away from the opening and allowed to freely explore for 5 min. Behaviour was monitored from above by a video camera connected to a computerized video tracking system (Anymaze). The apparatus was cleaned thoroughly between each trial. The number of transitions between the two compartments as well as the time spent and distance travelled in the lit room were measured as indications of anxiety-related behaviour. These measures were compared between mice housed in the T24 and T7 cycles using an unpaired Student's *t*-test.

Elevated plus maze. The apparatus consisted of two open arms (42 × 6 cm) opposite to one another and two arms enclosed by walls (42 × 6 × 14 cm) opposite

©2012 Macmillan Publishers Limited. All rights reserved

of one another forming a cross. The arms were separated by a central platform (6 × 6 cm). The maze was elevated (33 cm) such that the open arms convey openness, unfamiliarity and elevation. The light intensity in the open arms was ~600 lx, whereas the light intensity in the closed arms was ~200 lx. Mice were placed in the centre of the elevated plus maze facing one of the open arms. Behaviour was monitored from above by a video camera connected to a computerized video tracking system (Anymaze). The apparatus was cleaned thoroughly between each trial. The time spent and the distance travelled in the open arms were measured as indications of anxiety-related behaviour. These measures were compared between mice housed in the T24 and T7 cycles using an unpaired Student's *t*-test.

MWM. The water maze consisted of a circular pool (150 cm in diameter) with room temperature water (26–28 °C). The water was made opaque with the addition of non-toxic white tempura paint to hide the escape platform. The platform was made from PVC piping with a top (10 cm in diameter) painted white and submerged in the pool such that 1 cm of water covered the platform hiding it from sight. For visual trials, a flag made from a 50-ml conical tube covered with coloured tape was placed on the platform. During the acquisition, probe and reversal trials, four cues were attached to the side of the pool equidistant from one another, and the entire pool was surrounded by a plain curtain to block any other visual cues. Performance was scored using a video tracking system (Anymaze) with a camera mounted above the pool. The light intensity at the water surface was approximately 500 lx.

Mice were tested in four stages: visual, acquisition, probe and reversal (see Fig. 2a). Before spatial training, mice were trained to escape the pool using the visual flag located on top of the platform to familiarize them with the test. This was performed four times with an inter-trial interval of (30 min), and the platform was moved between each trial. We also used this visual training to screen for and remove animals that show floating behaviour in the water maze. Animals that floated in two or more trials during training were not tested in the spatial task to prevent confounds from floating behaviour. During the acquisition phase, mice were trained (one trial per day for 12 days) to find the hidden platform using the four visual distal cues surrounding the pool. The mouse was randomly placed in a different area of the pool at the start of each trial with the platform maintained in the same quadrant (target quadrant). The platform was removed on day 13 in the probe trial. The swimming in each quadrant and specifically the preference for the target quadrant was measured to evaluate spatial memory using a computerized video tracking system (Anymaze). Reversal training began on day 14 when the platform was moved to the quadrant opposite the original target quadrant. Mice were trained as described for the acquisition phase.

Latency to locate the platform during the acquisition and reversal phases was analysed by two-way ANOVA followed by a Bonferroni post-hoc test to examine changes in latency throughout the course of the experiment as well as the effect of light cycle exposure. Probe trial was analysed by calculating the percentage time spent in the target quadrant and performing a one-sample *t*-test to determine whether this was significantly above 25%.

Novel object recognition. Novel object recognition was composed of three stages: acclimation to the novel object arena, familiar object exposure and finally novel object exposure. Mice were first removed from their home cage, acclimated to the empty testing arena (light intensity of 500 lx) for 10 min, and subsequently returned to their home cage 24 h before including two objects in the arena. The day after acclimation, mice were returned to this arena with two identical objects that they could freely explore for 10 min, after which they were returned to their home cage for 1 h. At the end of the 1-h period, mice were placed back into the arena with one of the objects changed to a novel object, and were allowed to explore both the familiar and novel objects for 5 min. Behaviour was monitored from above by a video camera connected to a computerized video tracking system (Anymaze), and the percentage of time spent with each object was calculated. Wild-type mice spend more time with the novel object, however, mice with recognition memory deficits will not be able to distinguish the novel from the stable object. Objects had been previously tested to ensure that animals showed no initial preference for a particular object. The identity of the objects (familiar versus novel) was counterbalanced. The objects and arena were thoroughly cleaned between each trial to remove odour cues. Object recognition was analysed by calculating the percentage time spent with the novel object and performing a one sample *t*-test to determine whether this was significantly above 50%.

Slice electrophysiology. Coronal (0.4 mm) hippocampal slices were prepared as described[27] in ice-cold dissection buffer (2.6 mM KCl, 1.23 mM NaH_2PO_4, 26 mM $NaHCO_3$, 212.7 mM sucrose, 10 mM dextrose, 3 mM $MgCl_2$ and 1 mM $CaCl_2$, bubbled with 5% CO_2, 95% O_2). Recordings were done in a similar buffer but with the sucrose replaced by NaCl and the temperature raised to 30 °C. Synaptic responses were evoked at 0.33 Hz stimulating the Schaffer collaterals with 0.2-ms pulses (concentric bipolar electrodes, FHC), and recorded extracellularly in CA1 stratum radiatum. LTP was induced by TBS, consisting of one or four theta epochs delivered at 0.1 Hz. Each epoch, in turn, consisted of 10 trains of four pulses (at 100 Hz) delivered at 5 Hz. LTD was induced by low frequency stimulation (1 Hz, 15 min). These protocols were delivered after 20 min of stable baseline transmission. All hippocampal slice electrophysiological recordings were performed and analysed by an experimenter blind to the treatment of the animals. Two-way ANOVA was used to analyse fibre volley differences between the T7 and T24 treatments. The slopes for the linear fit of the fibre-volley–slope relationship were compared by *t*-test.

Fluoxetine administration. Mice were housed in either the T24 or T7 cycle for two weeks ($n = 20$ per group) with food and water *ad libitum*. For chronic treatment, this was followed by a 3-week treatment of 18 mg kg^{-1} day^{-1} of fluoxetine (Sigma). For subchronic treatment, this was followed by a 4-day treatment of 18 mg kg^{-1} day^{-1}. Fluoxetine was administered in the drinking water and control mice received tap water. Dosage was calculated based on the average amount of water consumed per day and mouse weight. Fluoxetine consumption was also measured during treatment to determine the amount consumed per mouse.

Period length measurement with fluoxetine treatment. Mice were housed under infrared motion detectors as described above. Mice were housed in the T7 light cycle for 2 weeks after which fluoxetine (18 mg kg^{-1} day^{-1}) was administered in the drinking water for 3 weeks. Circadian period was determined by fitting a regression line to the onsets of activity over a 7-day period. Period lengths before and after 3 weeks of fluoxetine treatment were compared by paired *t*-test.

Desipramine administration. Desipramine (Sigma) was dissolved in sterile water with 5% Tween-20. Each mouse received 16 mg kg^{-1} desipramine intraperitoneally 24- and 1-h before testing in the novel object recognition paradigm. The same volume of vehicle (water with 5% Tween-20) was administered intraperitoneally to control mice.

Statistical analysis. All statistical analysis was performed using GraphPad Prism. Specific tests used to analyse data are described their respective section of the methods.

Report

Acquiring "the Knowledge" of London's Layout Drives Structural Brain Changes

Katherine Woollett[1] and Eleanor A. Maguire[1,*]
[1]Wellcome Trust Centre for Neuroimaging, Institute of Neurology, University College London, 12 Queen Square, London WC1N 3BG, UK

Summary

The last decade has seen a burgeoning of reports associating brain structure with specific skills and traits (e.g., [1–8]). Although these cross-sectional studies are informative, cause and effect are impossible to establish without longitudinal investigation of the same individuals before and after an intervention. Several longitudinal studies have been conducted (e.g., [9–18]); some involved children or young adults, potentially conflating brain development with learning, most were restricted to the motor domain, and all concerned relatively short timescales (weeks or months). Here, by contrast, we utilized a unique opportunity to study average-IQ adults operating in the real world as they learned, over four years, the complex layout of London's streets while training to become licensed taxi drivers. In those who qualified, acquisition of an internal spatial representation of London was associated with a selective increase in gray matter (GM) volume in their posterior hippocampi and concomitant changes to their memory profile. No structural brain changes were observed in trainees who failed to qualify or control participants. We conclude that specific, enduring, structural brain changes in adult humans can be induced by biologically relevant behaviors engaging higher cognitive functions such as spatial memory, with significance for the "nature versus nurture" debate.

Results and Discussion

In order to qualify as a licensed London taxi driver, a trainee must learn the complex and irregular layout of London's ~25,000 streets (Figure 1) within a 6-mile radius of Charing Cross train station, along with the locations of thousands of places of interest. This spatial learning is known as acquiring "the Knowledge" and typically takes between 3 and 4 years, leading to a stringent set of examinations, called "appearances," which must be passed in order to obtain an operating license from the Public Carriage Office (PCO, the official London taxi-licensing body). This comprehensive training and qualification procedure is unique among taxi drivers anywhere in the world. Previous cross-sectional studies of qualified London taxi drivers documented more gray matter (GM) volume in their posterior hippocampi and less in their anterior hippocampi relative to non-taxi-driving matched control participants [2–4]. Moreover, correlation of hippocampal GM volume with years of taxi driving suggested that structural differences may have been acquired through the experience of navigating, to accommodate the internal representation of London, and were not merely due to preexisting hippocampal GM volume patterns disposing individuals to being taxi drivers [2–4, 19, 20]. As well as displaying a specific pattern of hippocampal GM volume, qualified taxi drivers have been found to display better memory for London-based information, but surprisingly poorer learning and memory for certain types of new visual information (e.g., delayed recall of complex figures), compared with control participants, suggesting there might be a price to pay for the acquisition of their spatial knowledge, perhaps linked to their reduced anterior hippocampal volume (see [3, 4, 20] for more on this). Interestingly, the opposite pattern of hippocampal GM volume and memory profile has been described in retired taxi drivers, hinting that any changes acquired through learning might be reversed or "normalized" when the call on stored memory representations lessens [21].

London taxi drivers are therefore a useful model of memory, illuminating the role of the hippocampus and intrahippocampal functional differentiation and potentially informing about whether hippocampal structure and memory capacity are hardwired or amenable to change. Given current economic imperatives and increasing longevity, the need to keep retraining and learning throughout adulthood has never been more acute. Direct evidence for hippocampal plasticity in response to environmental stimulation could allow us to understand the boundaries within which human memory operates and the scope for improving or rehabilitating memory in educational and clinical contexts. Moreover, given the dearth of longitudinal magnetic resonance imaging (MRI) structural association studies focusing on higher cognitive functions in average adults engaged in truly naturalistic behaviors, taxi drivers could contribute new information to the wider debate about whether key aspects of cognition are fixed or malleable.

The above aspirations are predicated upon hippocampal plasticity in adult humans, evidence for which remains sparse [10, 18]. We therefore conducted a longitudinal study examining 79 male trainee London taxi drivers at the start of their training (T1, time 1) and then again 3–4 years later just after qualification (T2, time 2), as well as 31 male control participants, with two aims. First, given that the PCO suggests that typically 50%–60% of trainees fail to qualify, we anticipated having three groups of participants: trainees who qualified (Q), trainees who failed to qualify (F), and the controls (C). With this design, we could retrospectively examine whether MRI and/or neuropsychological findings at T1 could predict who would eventually qualify 3–4 years later at T2. Second, we sought to ascertain whether the pattern of hippocampal GM volume and memory profile observed in previous cross-sectional taxi driver studies would be induced and observable within the same participants as a result of acquiring "the Knowledge."

Of the 79 trainees, 39 went on to qualify as licensed London taxi drivers, while 20 did not qualify (ceased training or failed their appearances) but agreed to return for testing at T2. Of the other 20 trainees who did not wish to return at T2, two had qualified, and the remaining 18 decided to stop training or made no appearances. Thus in our sample, 51.9% of trainees qualified, in line with PCO figures. All 31 control participants returned for testing at T2.

Time 1

We first focused on the data acquired at T1 and examined the status before training occurred of those trainees who subsequently qualified or not, as well as the control participants. There were no statistically significant differences between the three groups on a range of background measures such as age, handedness, education, and IQ [$F(8,166) = 1.81$; $p = 0.07$; see Table 1]. We next looked at their performance at T1 on a battery of tests assessing working and long-term memory, recognition and recall, and visual and verbal material (see Supplemental Experimental Procedures and Table S1A available online). There were no statistically significant differences between the three groups for any of the memory measures [$F(18,158) = 1.33$; $p = 0.18$]. Finally, we examined the structural MRI brain scans of participants acquired at T1, before training. An automated whole-brain analysis method, voxel-based morphometry (VBM; [22, 23]) implemented in SPM8, was used to compare GM volume between the groups. No significant differences were found, even with a liberal statistical threshold ($p < 0.005$ uncorrected for multiple comparisons).

Our data therefore showed that at T1, before acquisition of a detailed internal spatial representation of London's layout, there was no general intellectual, mnemonic, or structural brain difference that was associated with subsequent success at qualification. In particular, hippocampal GM volume, both anteriorly and posteriorly, was indistinguishable between those who would qualify, those who would not, and the controls. This means that the groups started out on equal terms and that any changes that subsequently emerged would be due to acquiring "the Knowledge."

Time 2

In the first instance, we compared the two trainee groups on a range of training-related variables (see Table 1). There was no significant difference between those who qualified and those who did not in terms of the total time they had spent in training [$t(57) = 0.67$; $p = 0.5$]. There was a difference, however, in the number of hours per week the groups spent training, with the trainees who qualified spending twice as many hours per week training compared to the group who failed to qualify [$t(57) = 6.62$; $p = 0.001$]. Unsurprisingly, the two groups differed also in the number of appearances that they made, with the failed candidates making hardly any [$t(57) = 13.1$; $p = 0.001$]. Finally, there was no significant difference in the time elapsed between testing at T1 and testing at T2 for the Q, F, and C groups [$F(2, 86) = 1.27$; $p = 0.28$].

We next examined performance at T2 on parallel versions of the memory tests that had first been employed at T1 (see Table S1B). Whereas at T1 there were no differences between

Table 1. Background Characteristics of the Participants

Measure	Qualified (n = 39)	Failed to Qualify (n = 20)	Controls (n = 31)
Age (years)	37.97 ± 7.96	40.50 ± 5.27	35 ± 8.99
Age left school (years)	16.66 ± 1.32	16.75 ± 1.40	16.77 ± 1.30
Estimated verbal IQ	97.72 ± 6.29	98.66 ± 3.49	100.79 ± 3.79
Matrix reasoning (scaled score)	11.89 ± 2.06	12.20 ± 1.98	11.83 ± 2.39
Handedness (laterality index)	87.97 ± 24.09	88.10 ± 21.50	71.74 ± 38.69
Total training time (months)	38.84 ± 7.02	35.80 ± 10.32	–
Training time per week (hours)[a]	34.56 ± 12.40	16.70 ± 8.21	–
Number of appearances[a]	15.64 ± 3.66	2.60 ± 3.45	–
Time between T1 and T2 testing (months)	35.28 ± 8.19	36.15 ± 8.53	32.8 ± 7.37

Measurements are given in means ± SD.
[a] Significantly more for trainees who qualified compared to trainees who did not qualify.

the groups, at T2 this was no longer the case: significant differences between the three groups now emerged [$F(18,158) = 2.35$; $p = 0.004$], driven by two main effects. A significant difference was found between the groups on the London landmarks proximity judgments test [$F(2,87) = 8.09$ $p = 0.001$], with trainees who qualified being significantly better at judging the spatial relations between London landmarks than the control participants ($p = 0.003$), as were nonqualified trainees ($p = 0.003$). The groups also differed on the delayed recall of the Taylor complex figure [$F(2,87) = 4.38$; $p = 0.015$], with qualified trainees being significantly worse at recalling the complex figure after 30 min delay than the control participants ($p = 0.01$). By contrast, the performance of the nonqualified trainees was not significantly different from that of control participants ($p = 0.14$).

The memory profile displayed by the now qualified trainees mirrors exactly the pattern displayed in several previous cross-sectional studies of licensed London taxi drivers [3, 4, 20] (and that which normalized in the retired taxi drivers [21]). In those studies also, the taxi drivers displayed more knowledge of the spatial relationships between landmarks in London, unsurprisingly, given their increased exposure to the city compared to control participants. By contrast, this enhanced spatial representation of the city was accompanied by poorer performance on a complex figure test, a visuospatial task designed to assess the free recall of visual material after 30 min. Our findings therefore not only replicate those of previous cross-sectional studies but extend them by showing the change in memory profile within the same participants. That the only major difference between T1 and T2 was acquiring "the Knowledge" strongly suggests that this is what induced the memory change.

We then turned to the structural MRI brain scans acquired at T2 and compared them to the scans acquired in the same individuals at T1 in order to assess whether acquiring "the Knowledge" had any impact on GM volume. This was accomplished by implementing high-dimensional warping (HDW) in SPM8. HDW safeguards against nonspecific subtle differences that may arise between the first and second scans within subjects in a longitudinal study (see Supplemental Experimental Procedures and also [24] for full details). The time between scans, total GM volume, and participant age were modeled as confounding variables. Given our a priori interest in the hippocampus, the significance level was set at $p < 0.001$ corrected for the volume of the hippocampus; otherwise the significance level was set at $p < 0.05$ corrected for multiple comparisons across the whole brain. We first looked at the scans of the qualified trainees and found that GM volume had increased in the posterior hippocampi bilaterally (30, −42, 1, $z = 5.44$; 20, −37, 10, $z = 5.64$; 24, −39, 7, $z = 4.02$; −29, −42, 3, $z = 5.91$) at T2 relative to T1 (see Figure 2 and Figure 3). The opposite comparison (T1 > T2) did not show any significant differences, nor were there any significant differences in GM volume anywhere else in the brain for either contrast. Similar analyses were performed for the trainees who failed to qualify. No significant differences in GM volume were found anywhere in the brain, including the hippocampi, for T2 > T1 or T1 > T2. When the data from the two time points of the control participants were compared, again no significant differences in GM volume emerged.

As with the memory data, the structural MRI brain data replicate and extend the cross-sectional taxi driver studies [2–4] by showing that the increased posterior hippocampal GM volume previously observed most likely occurred as a result of acquiring the detailed spatial representation of London's layout. Importantly, the posterior hippocampal change in GM volume cannot be attributed to the qualified trainee taxi drivers' training procedures, methods, or general attempts to learn, as the trainees who failed to qualify were exposed to the same milieu. Although the posterior hippocampal increase accords with previous findings, we did not observe a decrease in anterior hippocampal GM volume. This is interesting, because it may provide an insight into the time frame of the hippocampal structural changes. It could be that they occur serially, with the increase in posterior hippocampus happening first and within 3–4 years. We speculate that the anterior hippocampal GM volume might then decrease subsequently and in response to the posterior increase. In fact, the poor performance of the qualified trainees on the delayed recall of the complex figure at T2 may be an indication that changes are already afoot in the anterior hippocampus but are not yet detectable with MRI.

That acquiring "the Knowledge," which encompasses spatial learning and memory, can drive changes in posterior hippocampus illustrates the close relationship between this region and spatial navigation [25–27] and suggests that the hippocampus acts as a storage site for the spatial information acquired during "the Knowledge," or as a processing hub for detailed navigational information. Our results underline the existence of functional differentiation in the hippocampus, with anterior and posterior regions diverging in their response to spatial memory [28, 29]. The hippocampal plasticity we have observed in vivo in adult humans parallels the effects reported in nonhumans where intraindividual hippocampal volume changes occur in response to demands placed on spatial memory [30, 31]. Having documented this hippocampal change, the question is what mechanism underpins this process.

Using standard structural MRI scanning in humans, it is not possible to address this question directly, but based on work in nonhumans, there are several candidates. Studies in rodents have demonstrated that when learning requires cognitive effort and where learning actually takes place (i.e., where material is remembered after a delay), there is an effect on the rate of hippocampal neurogenesis [32]. Moreover, the animals that learn best have more new neurons after training

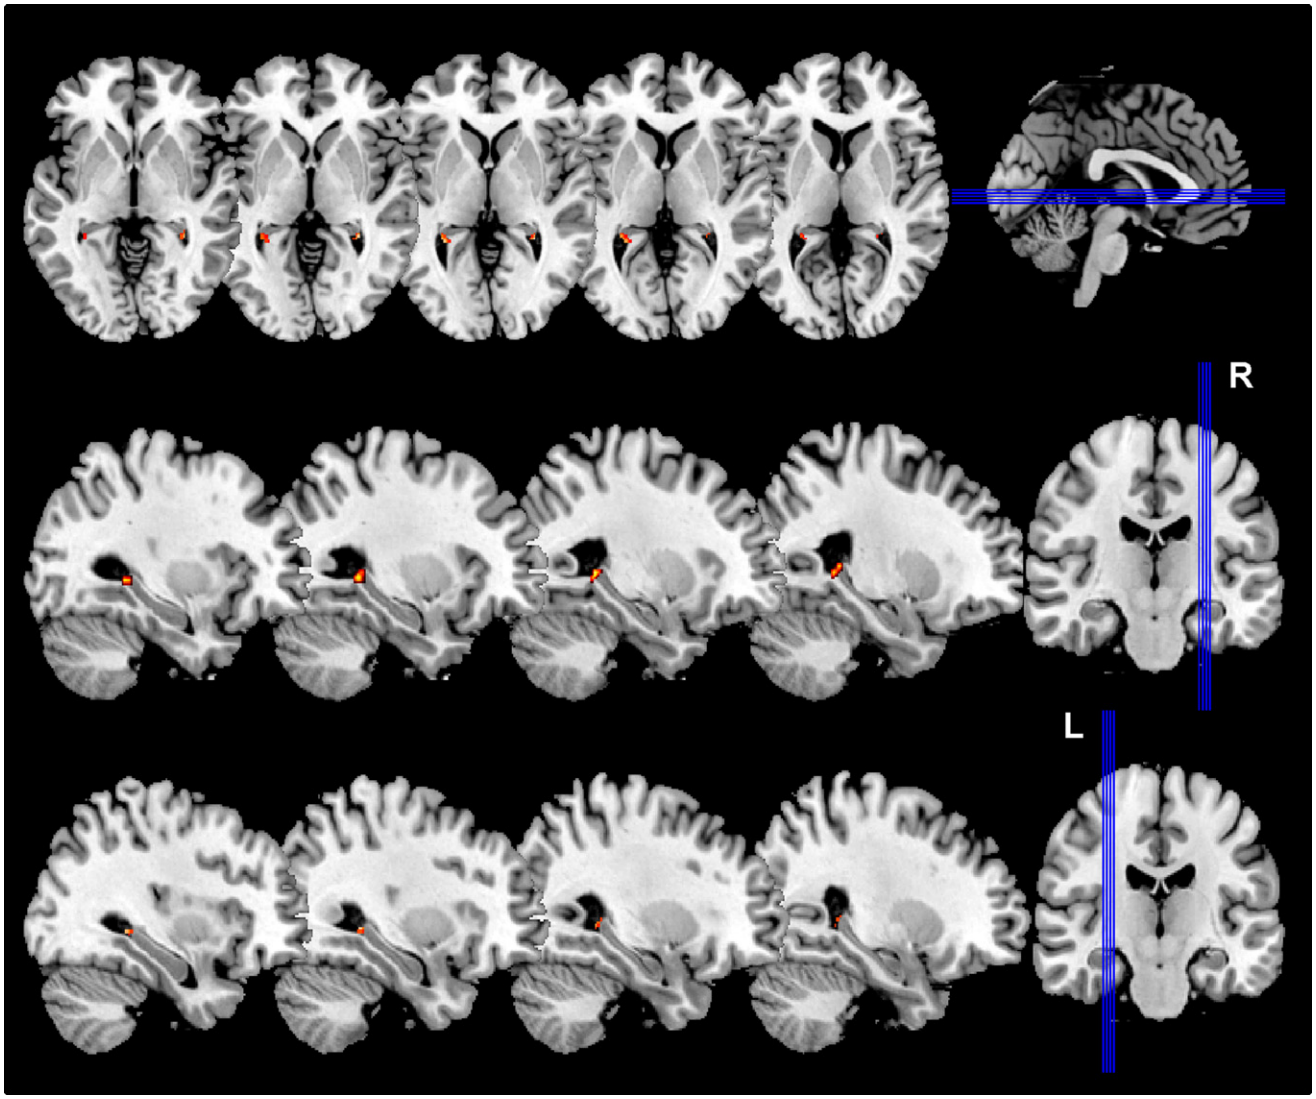

Figure 2. Gray Matter Volume Changes between T1 and T2 in Qualified Trainees

Gray matter (GM) volume increased in the most posterior part of the hippocampus bilaterally between T1 and T2 as a result of acquiring a detailed representation of London's layout. This change was only apparent in the trainees who qualified. The upper row shows axial views, and the middle and lower rows show sagittal views through the right (R) and left (L) sides of the brain, respectively, that encompass the GM changes (shown in orange and yellow) in the peak voxels detailed in the text.

than those who do not learn, or do not learn efficiently [33, 34]. If neurogenesis is what underpins the hippocampal volume change in qualified taxi drivers, it may be related to recruitment of new neurons following neurogenesis [35, 36] that are pressed into the service of spatial memory. The development of greater communication between neurons in the form of increased synaptogenesis [37, 38] might also be involved, and proliferation in dendritic arborization, augmenting connectivity between neurons, could in turn increase memory capacity and also lead to volumetric changes [39]. Glial cells, which continue to be produced, albeit at a slow pace, throughout adulthood [40], could also be implicated and have been shown to increase in volume with the addition of synapses following learning [41]. In the future, new approaches to human brain scanning in vivo may eventually be able to provide more direct insight into the key mechanisms supporting human hippocampal plasticity [42].

To conclude, we have shown that there is a capacity for memory improvement and concomitant structural changes to occur in the human brain well into adulthood. That there are many thousands of licensed London taxi drivers shows that acquisition of "the Knowledge," and presumably the brain changes that arise from it, is not uncommon, offering encouragement for lifelong learning, and possibly a role in neurorehabilitation in the clinical context. However, this needs to be balanced by our finding that memory improvement in one domain may come at the expense of memory performance elsewhere. One final point to consider concerns the PCO figures and our data showing that only half of trainees who undertake "the Knowledge" actually qualify. The reasons we were given for ceasing training included the time commitment being too great, financial imperatives, and family obligations. Very few trainees reported ceasing because they found the spatial memory demands to be too great, although it is possible, or

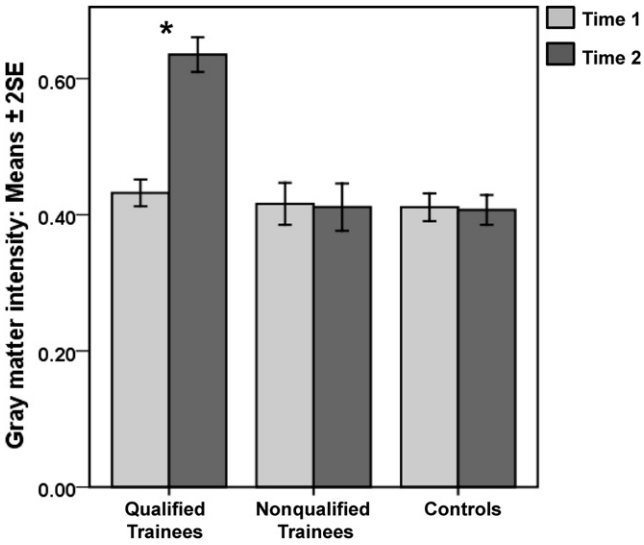

Figure 3. Plot of Gray Matter Intensities across Groups and Time

GM intensity values were extracted from the four peak hippocampal voxels identified by the HDW procedure (see text for details). Here we show a plot from one of those peaks (the others resulted in very similar plots) at 20, −37, 10 in the right posterior hippocampus. Only the qualified trainees experienced a significant increase in posterior hippocampal gray matter between T1 and T2; this change was evident in every qualified trainee. Data are presented as means ± two standard errors of the mean. *$p < 0.05$.

even likely, that the reasons given may have masked such difficulties in some individuals. It could be that there are inherited factors that feed into individual differences in spatial memory and navigation ability. One source of influence may come from genes. Genetic association studies have demonstrated effects of specific gene polymorphisms on the volume of the hippocampus [43, 44] and memory performance [45, 46]. Although our data show that environmental stimulation can drive structural brain changes, it may be that this hippocampal plasticity expresses itself only in certain individuals. The trainees that qualified may have had a genetic predisposition toward plasticity that the nonqualified individuals lacked. Thus, the perennial question of "nature versus nurture" is still open for future investigations that incorporate genetic and other influences on individual differences, as well as cognitive and structural brain dimensions.

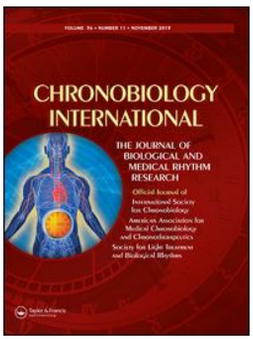
Experimental Procedures

All participants gave informed written consent to participation in accordance with the local research ethics committee. Full details of the participants, cognitive tests, MRI scans, and data analysis procedures are provided in the Supplemental Experimental Procedures.

Supplemental Information

Supplemental Information includes one table and Supplemental Experimental Procedures and can be found with this article online at doi:10.1016/j.cub.2011.11.018.

Acknowledgments



This work was supported by the Wellcome Trust. We thank all participants for their time and continued interest throughout the study. We are very grateful to the Public Carriage Office, in particular Tony Bishop and Alison Said. Thanks also to the Knowledge Schools, the Physics and Imaging Support teams at the Wellcome Trust Centre for Neuroimaging, Ralf Deichmann, Amanda Brennan, John Ashburner, Jenny Crinion, Alex Leff, Ric Davis, and Chris Freemantle.

ABSTRACT

Previous studies have found that keeping the room dark at night was associated with a decrease in manic symptoms for patients with bipolar disorder (BD). However, the association between light at night of real-life conditions and manic symptoms is unclear. We investigated the association between bedroom light exposure at night and manic symptoms in BD patients. One-hundred and eighty-four outpatients with BD participated in this cross-sectional study. The average light intensity at night during sleep was evaluated using a portable photometer for seven consecutive nights. Manic symptoms were assessed using the Young Mania Rating Scale (YMRS), and scores ≥5 were treated as a "hypomanic state." The median (interquartile range) YMRS score was 2.0 (0–5.0), and 52 (28.2%) participants were in a hypomanic state. The prevalence of a hypomanic state was significantly higher in the participants with an average light intensity at night exposure of ≥3 lux than in those with <3 lux (36.7% versus 21.9%; $P = .02$). In multivariable logistic regression analysis adjusted for BD type, depressive symptoms, sleep duration, and daytime physical activity, the odds ratio (OR) for a hypomanic state was significantly higher for the participants with an average light intensity at night exposure of ≥3 lux than for those with <3 lux (OR: 2.15, 95% confidence interval: 1.09–4.22, $P = .02$). This association remained significant at the cutoff value of YMRS score ≥6 (OR: 2.51, 95% confidence interval: 1.15–5.46; $P = .02$). The findings of this study indicate bedroom light exposure at night is significantly associated with manic symptoms in BD patients. Although the results of this cross-sectional investigation do not necessarily imply causality, they may serve to inform beneficial nonpharmacological intervention and personalized treatment of BD patients.

KEYWORDS
Bipolar disorder; manic symptom; light at night; dark; circadian rhythm

Introduction

Bipolar disorder (BD) is a severe chronic mental illness with a prevalence of 1–4%, which is characterized by episodes of depression and mania/hypomania (Merikangas et al. 2007). Manic or hypomanic episodes are states of elevated mood and increased activity or energy, and most patients complain of a reduced need for sleep during manic episodes (Harvey 2008). Patients with an acute manic episode often present with psychotic symptoms (Goodwin 2007), which increase the risk of a subsequent depressive episode (Salvadore et al. 2010). Symptoms during manic episodes cause impairment of social, economic, and professional functioning, leading to the possibility of hospitalization (Grande et al. 2016). Therefore, management of manic symptoms is of great clinical importance.

Light exposure, including seasonality and photoperiod, is closely associated with the pathophysiology of BD, such as altered mood symptoms, circadian rhythms, and sleep quality as well as risk suicide and hospitalization in emergency psychiatry (Aguglia et al. 2017, 2018; Geoffroy 2018; Aguglia et al. 2019; Bauer et al. 2019; Esaki et al. 2019a, b). For this reason, light regulation is widely used in the treatment of BD. Light therapy exposes patients to bright artificial light in the morning (Pail et al. 2011), and various studies have found that it is effective for bipolar depression (Sit et al. 2018; Tseng et al. 2016; Zhou et al. 2018). In contrast, darkness at night while sleeping is associated with reduction of manic symptoms in BD (Barbini et al. 2005). Findings from two case reports and one pilot study indicate that dark

therapy (DT), which exposes patients to a dark room from 18:00 to 08:00 h, can exert striking beneficial effects on manic patients (Barbini et al. 2005; Wehr et al. 1998; Wirz-Justice et al. 1999). Additionally, a recent randomized placebo-controlled study demonstrated that virtual DT using blue-blocking glasses from 18:00 to 08:00 h significantly reduces mania scores relative to the scores attained with placebo glasses (Henriksen et al. 2016). Collectively, the results of these past investigations imply depression improves with morning/daytime light, whereas mania decreases with evening/nighttime darkness.

Although artificial light has great benefits for modern daily life, exposure to light at night (LAN) is associated with negative health effects, such as cancer, metabolic syndrome, mood disorders, and sleep disorders (Cho et al. 2015). It is likely that LAN exposure may affect manic symptoms in BD patients. However, to the best of our knowledge, no study has investigated the association between LAN exposure and manic symptoms in patients with BD. In this cross-sectional study, we evaluated the associations between bedroom LAN exposure and manic symptoms in patients with BD. We hypothesized that LAN exposure is associated with worsening of manic symptoms.

Materials and methods

Participants

Between August 2017 and January 2019, outpatients with BD participated in a study titled "Association between the Pathology of Bipolar Disorder and Light Exposure in Daily Life (APPLE) cohort study" from Okehazama Hospital, Fujita Mental Care Satellite Zengo, Fujita Mental Care Satellite Tokushige, and Fujita Health University. Eligible patients were 18–75 years old and had a diagnosis of BD I or II according to the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (American Psychiatric Association 2013). Primary analysis did not exclude pregnant patients or those who had other co-existing psychiatric diagnoses/conditions (e.g., personality disorders, substance abuse, and mental retardation), neurological disorders, and other diseases. Night-shift workers and those judged by a clinician to be at serious suicidal risk were excluded. A total of 370 participants were assessed for eligibility. Among them, 49 patients did not meet the inclusion criteria, and 131 patients refused to participate in the study. Therefore, a total of 190 patients were enrolled in this study. Five patients discontinued the study because of difficulty with the photometric measurement, and one patient could not be evaluated for mood symptoms. Finally, a total of 184 patients were analyzed in this study. The study procedure was approved by the ethics committee of Okehazama Hospital and was performed in accordance with the tenets of the Declaration of Helsinki and the ethical standards of the journal (Portaluppi et al. 2010). All participating patients provided written informed consent, and the study was registered at UMIN-CTR (identifier: UMIN000028239).

Study procedure

We evaluated the demographic and clinical characteristics of the participants at the clinic, and then instructed them to perform the following procedures and measurements for 7 consecutive days: (1) record bedroom light from bedtime to rising time using a portable photometer (LX-28SD; Sato Shouji Inc., Kanagawa, Japan) and (2) record bedtime and rising time in a sleep diary. Bedtime was defined as the point in time when the participant was in bed and intended to go to sleep and did not start if the participant was in bed reading books or watching TV. Rising time was defined as the point in time when the participant actually got out of bed.

LAN exposure assessment

LAN exposure in the bedroom was recorded at 1-min intervals using the photometer. We instructed the participant to position the light sensor of the photometer near their head at eye level and to start the recording at bedtime and end it at final rising time. We defined the average light intensity at night over the entire period from bedtime to rising time as the average LAN exposure. A previous experimental study reported that a LAN exposure ≥3 lux affected the circadian rhythm of healthy adults (Zeitzer et al. 2000). Additionally, another experimental study has

shown that LAN of ≥5 lux during sleep might affect the sleep architecture of healthy young men (Cho et al. 2016). Thus, we used the value of 3 lux as a cutoff threshold in this study. The procedure for measuring LAN exposure has been used in previous studies of the general population as well as patients with BD (Esaki et al. 2019b; Obayashi et al. 2012).

Manic symptoms' assessment

Manic symptoms were evaluated at the start of the experimental period using the Young Mania Rating Scale (YMRS) (Young et al. 1978). The YMRS is an 11-item diagnostic questionnaire used to measure the severity of manic symptoms in patients with BD; the overall score ranges from 0 to 60. A higher YMRS score indicates more severe mania. The International Society for Bipolar Disorders (ISBD) Task Force recommends a YMRS score of <5 as symptomatic remission of bipolar mania (Tohen et al. 2009). Therefore, as used herein, a YMRS score ≥5 points is indicative of a "hypomanic state." Additionally, we also used different cut off points (YMRS score ≥6 and ≥13) because a definition of remission in BD varied and were inconsistent.

Other assessment

Depressive symptoms were evaluated at the start of the experimental period using the Montgomery–Åsberg Depression Rating Scale (MADRS) (Montgomery and Asberg 1979). Sleep duration, daytime physical activity, and daytime light exposure were evaluated using actigraphy (Actiwatch Spectrum Plus; Respironics Inc., Pittsburgh, PA, USA). The participants were instructed to wear an actigraph on the wrist of their non-dominant arm 24 h/day, except while bathing and during aquatic activities, for 7 consecutive days. We used a default threshold as wake (≥40 counts per min) and sleep periods (<40 counts per min). This threshold setting has been validated to be as accurate as polysomnography in measuring sleep in patients with BD (Kaplan et al. 2012). Sleep duration was the total time from sleep start to end. Daytime physical activity was defined as the average activity count per minute from rising time to bedtime. Average daytime light was defined as the average daytime light intensity from rising time to bedtime. The information on psychiatric medications, including mood stabilizers (lithium, lamotrigine, valproate, and carbamazepine), antipsychotics, antidepressants, and hypnotics were obtained from the clinical records. Data of the day length from sunrise to sunset in Aichi (latitude, 35° N) on the first measurement day of each subject were collected from the web page of the National Astronomical Observatory of Japan. Sociodemographics, including married status and employment status, were obtained from the questionnaire. Clinical characteristics, including type of BD, age at onset of BD, duration of illness, and family history of psychiatric disorders, were obtained from the clinical records or the participants' doctors.

Statistical analyses

Normally distributed variables are presented as the mean and standard deviation (SD), those with an asymmetrical distribution as median and interquartile range (IQR), and categorical variables as number and percentage. The night-to-night correlations of LAN exposure during the 7 days study span were evaluated using the Spearman's rank correlation coefficient (*rs*). In comparisons between the hypomanic state and non-hypomanic state groups, unpaired t-tests, Mann–Whitney U test, Fisher's exact test, and chi-square test were used to compare their demographic characteristics (age, sex, marital status, and employment), clinical characteristics (type of BD, age at onset of BD, duration of illness, psychiatric comorbidity, family history, MADRS and YMRS scores, bedtime, rising time, sleep duration, daytime physical activity, average daytime light, and day length), and psychiatric medications (mood stabilizers, antipsychotics, antidepressants, and hypnotics).

Associations of average LAN (≥3 versus <3 lux) with manic symptoms (median YMRS scores and prevalence of hypomanic state [YMRS score ≥5], YMRS score ≥6 and ≥13) were evaluated using the Mann–Whitney U test and chi-square test, respectively. Odds ratios (ORs) for a hypomanic state and YMRS score ≥6 were evaluated using the univariable and multivariable logistic regression model, respectively. The MADRS score was not normally distributed, even after log transformation. It was, therefore, treated as a categorical variable in the logistic

regression analyses as being either above or below a cutoff value of 8 points (the cutoff value for depression recommended by the ISBD Task Force) (Tohen et al. 2009). In the multivariable model, the ORs were simultaneously adjusted for variables associated with mania chosen based on previous studies, including type of BD (I or II) (Judd et al. 2003, 2002), MADRS score (≥8 or <8) (Judd et al. 2003, 2002), sleep duration (in min) (Salvatore et al. 2008), and daytime physical activity (in count/min) (Krane-Gartiser et al. 2014). Statistical analyses were performed using SPSS version 25.0 for Windows (IBM Corp., Armonk, NY). A two-sided p value < .05 was considered as indicative of statistical significance.

Results

Of the total 184 participants, 103 (56%) were female, and 81 (44%) were male, with a mean (SD) age of 45.1 (13.1) years. The median (IQR) of the YMRS scores was 2.0 (0–5.0), and 52 (28.2%) participants were classified as being in a hypomanic state during the 7-day study period. Among these 52 participants, 19 (36.6%) were in a hypomanic state (YMRS score ≥5 and MADRS score <8), and 33 (63.4%) were in a mixed state, including a depressive state (YMRS score ≥5 and MADRS score ≥8). The median (IQR) of the average LAN exposure was 2.0 (0.3–9.5) lux; 79 (42.9%) participants had an average LAN exposure of ≥3 lux, and 105 (57.1%) had exposure of <3 lux. The night-to-night correlations of the LAN exposure throughout the 7 days study span were moderate (*rs* range: 0.55–0.72).

As shown in Table 1, the median MADRS score was significantly higher in the hypomanic state group than in the non-hypomanic state group (12.0 versus 8.0; P = .03). Sleep duration was significantly shorter in the hypomanic state group than in the non-hypomanic state group (413.4 versus 450.6 min; P = .01).

The prevalence of the hypomanic state (YMRS score ≥ 5) was significantly higher in the participants with average LAN ≥ 3 lux than in those with <3 lux (36.7% versus 21.9%; P = .02, Figure 1). This association remained significant at different cutoff values of the YMRS score (YMRS score ≥6: 27.3% versus 14.3%; P = .02, YMRS score ≥13: 8.9% versus 1.0%; P = .009). Consistently, the median (IQR) YMRS score was 3.0 (1.0–6.0) in the participants with an average LAN exposure of ≥3 lux and was 2.0 (0–4.0) in those with <3 lux (P < .01). Additional analysis excluding participants with psychiatric comorbidity (n = 48) suggested that these associations remained significant (hypomanic state: 34.5% versus 17.9%; P = .02; YMRS score ≥ 6: 29.3% versus 12.8%; P = .01; YMRS score ≥13: 10.3% versus 1.3%; P = .01; median YMRS score: P = .01).

In univariable logistic regression analysis, crude ORs for a hypomanic state were significantly associated with the average LAN exposure and sleep duration (LAN: OR, 2.068; 95% CI: 1.079–3.963, P = .029; sleep duration: OR, 0.996; 95% CI: 0.992–0.999, P = .021; Table 2). In multivariable logistic regression analysis after adjusting for type of BD, MADRS score, sleep duration, and daytime physical activity, increased average LAN exposure was associated with higher adjusted OR for a hypomanic state (OR, 2.152, 95% CI: 1.095–4.228; P = .026, Table 2). Consistent with this, the crude and adjusted OR for YMRS score ≥6 were significantly associated with average LAN exposure (crude OR, 2.316, 95% CI: 1.110–4.831; P = .025; adjusted OR, 2.517, 95% CI: 1.158–5.468; P = .020, Supplemental Table 1).

Discussion

To our knowledge, this is the first study that has investigated the associations between LAN exposure in the real-life situation and manic symptoms in BD. We demonstrated that average LAN intensity was significantly associated with manic symptoms in patients with BD. This association was independent of potentially confounding factors, including type of BD, depressive symptoms, sleep duration, and daytime physical activity.

The study results are consistent with those of previous studies on the effectiveness of DT in bipolar mania. One previous study reported that adjunctive DT achieved a 50% reduction in the YMRS scores in 3 days for 16 patients with an acute manic episode (Barbini et al. 2005). Two case reports also showed that DT rapidly improved mood swing in rapid cycling patients (Wehr et al. 1998; Wirz-Justice et al. 1999). Furthermore, a recent randomized controlled trial involving 32 patients with bipolar mania demonstrated that

Table 1. Demographic and clinical characteristics between the hypomanic state and non-hypomanic state groups.

Variables	Hypomanic state (n = 52)	Non-hypomanic state (n = 132)	P
Demographic characteristics			
Age, years, mean (SD)	45.5 (12.0)	44.9 (13.6)	0.76
Sex, female, n (%)	32 (61.5)	71 (53.8)	0.34
Married, n (%)	29 (55.8)	68 (51.5)	0.60
Employed, n (%)	16 (31.4)	57 (43.2)	0.14
Clinical characteristics			
Type of BD, BD I, n (%)	21 (40.4)	45 (34.1)	0.42
Age at onset of BD, years, mean (SD)	31.2 (10.5)	32.9 (12.8)	0.39
Duration of illness, years, mean (SD)	14.3 (9.4)	12.0 (9.3)	0.14
Psychiatric comorbidity, n (%)	18 (34.6)	30 (22.7)	0.09
Family history of psychiatric disorders, n (%)	10 (19.2)	21 (15.9)	0.58
MADRS score, points, median (IQR)	12.0 (6.0–16.7)	8.0 (2.0–13.0)	0.03
YMRS score, points, median (IQR)	7.0 (5.0–9.0)	1.0 (0–2.0)	<0.01
Bedtime, clock time, mean (SD)	23:28 (1:58)	23:07 (1:35)	0.22
Rising time, clock time, mean (SD)	7:02 (2:03)	7:18 (1:47)	0.38
Sleep duration, min, mean (SD)	413.4 (84.0)	450.6 (100.0)	0.01
Daytime physical activity, counts/min, mean (SD)	188.1 (68.6)	171.1 (69.4)	0.15
Average daytime light, lux, median (IQR)	244.3 (175.2–315.5)	217.0 (150.3–308.4)	0.28

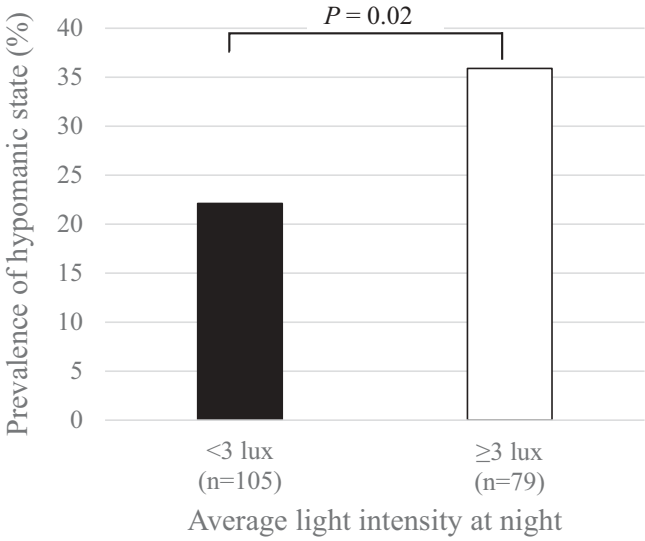

Figure 1. Associations of average light intensity (≥3 versus <3 lux) at night with prevalence of hypomanic state. P value is for the analysis using the chi-square test.

blue-blocking glasses therapy, which is virtual DT, relative to placebo glasses significantly improved YMRS score (Cohen's d = 1.86) (Henriksen et al. 2016). Our results indicated participants exposed to an average LAN ≥3 lux had an OR for manic symptom approximately two times higher than that for those exposed to an average LAN <3 lux. Although more than half the participants in the hypomanic state group had depressive symptoms (mixed state), the multivariable analysis demonstrated that the association between LAN exposure and manic symptoms were independent of depressive symptoms.

We also observed that shorter sleep duration was associated with increased mania, independently of average LAN, age, type of BD, and daytime physical activity. In a previous review study, 69–99% of the patients during the manic state complained of a reduced need for sleep in self-reported data, and polysomnography confirmed the decreased time spent asleep and shortened rapid eye movement sleep latency in the manic state (Harvey 2008). Additionally, another study reported that 32 patients with manic/mixed state experienced shorter total sleep time measured by actigraphy than that of 36 patients in a recovery

Table 2. Logistic regression analysis for the associations of each variable with odds ratios (ORs) for a hypomanic state.

Variables	Crude OR	95% CI		*P*	Adjusted OR	95% CI		*P*
Average LAN (≥3 versus <3 lux)	2.068	1.079	3.963	0.029	2.152	1.095	4.228	0.026
Type of BD (I versus II)	1.30	0.67	2.53	0.42	1.38	0.68	2.78	0.36
MADRS score (≥8 or <8 points)	1.63	0.84	3.16	0.14	1.71	0.84	3.50	0.13
Sleep duration (per min)	0.996	0.992	0.999	0.021	0.996	0.992	1.000	0.039
Daytime physical activity (per counts/min)	1.00	0.99	1.00	0.15	1.004	0.99	1.00	0.36

OR, odds ratio; CI, confidence interval; LAN, light at night. Adjusted for all covariates shown.

state (mean; 7.03 versus 8.54 h) (Salvatore et al. 2008). Our results showed that the participants in a hypomanic state had shorter sleep duration than that of the participants in a non-hypomanic state (mean; 413 versus 450 min). Therefore, our results are consistent with those of the previous study.

Our findings indicate that maintaining darkness during sleep could be a novel clinical therapeutic option for BD. Although pharmacological and nonpharmacological treatments for BD are progressing, one-third to one-half of patients with BD experience recurrence within 1 year (Gitlin et al. 1995; Keller et al. 1993; Perlis et al. 2006). A new treatment option is needed because, although DT is effective in bipolar mania, it is difficult for manic patients to maintain a dark room from 18:00 to 08:00 h (Wirz-Justice and Terman 2016). We consider that it may be possible for manic patients to maintain bedroom darkness only during sleep. Therefore, maintaining darkness during sleep is expected to have a beneficial or even curative effect on manic patients and a preventive effect on relapse of manic episodes. Further research using a longitudinal controlled study design is needed to determine the association between LAN exposure and manic symptoms.

The mechanism underlying the association between LAN exposure and manic symptoms in BD remains unknown, but it may be related to circadian rhythm dysfunction and sleep disturbance. Light exposure has a primary role in the regulation of circadian rhythms in humans (Dumont and Beaulieu 2007), and LAN exposure causes disruption of the biological clock and suppression of melatonin secretion (Lunn et al. 2017; Reiter et al. 2007; Smolensky et al. 2016, 2015). Furthermore, BD has been suggested to associate with the abnormality of circadian rhythm, including evening preference, light hypersensitivity, and the abnormal of melatonin and cortisol secretions (Bellivier et al. 2015; Geoffroy 2018). A previous longitudinal study demonstrated that BD patients with circadian rhythm sleep disorder (CRSD) had higher relapse of depressive, manic, or hypomanic episodes than those without CRSD (Takaesu et al. 2018). Therefore, circadian rhythm dysfunction is one of the major factors of the association between LAN exposure and mania. Another possible mechanism is sleep disturbance. Although LAN exposure is linked to variable negative health effects, sleep disturbance is one of the most obvious negative effects of LAN exposure (Cho et al. 2015). The association between LAN exposure and sleep disturbance has been reported not only from an experimental study but also from a study involving subjects with real-life situations (Cho et al. 2016; Obayashi et al. 2014). Sleep disturbance, particularly sleep loss, is associated with the risk for manic/hypomanic episodes (Lewis et al. 2018, 2017). Similarly, we observed a high OR for manic symptomatology in the participants with shorter sleep duration (Table 2). Therefore, it is likely that sleep disturbance may be involved in the association between LAN exposure and manic symptoms, although this association was independent of sleep duration measured using actigraphy. Various methods of evaluating sleep have been performed, including sleep diary, questionnaire, and polysomnography (PSG); in particular, PSG can evaluate not only sleep continuity but also its architecture. Thus, further studies using PSG are needed to clarify whether sleep mediates between LAN exposure and manic symptoms in BD.

This study had several limitations. First, this was a cross-sectional study; therefore, the results do not necessarily imply that LAN exposure worsens manic symptoms in patients with BD. Similarly, the causal relationship of LAN exposure and sleep duration is also unclear. Further longitudinal investigation is necessary to clarify these associations. Second, the

study participants were not randomly selected. The results may therefore have been affected by selection bias. Third, the YMRS score of participants in our study was low. In previous conducted DT and virtual DT studies, mean (SD) YMRS scores at the start of intervention were, respectively, 31.62 (10.92) and 23.4 (8.0) (Barbini et al. 2005; Henriksen et al. 2016). On the other hand, the median (IQR) YMRS score in the hypomanic state group of our study was 7.0 (5.0–9.0). It was difficult to recruit outpatients with acute manic symptoms in our study, because they are usually hospitalized until their condition improves. Therefore, this factor may have led to the underestimation of the association between LAN exposure and manic symptoms. Additionally, although we defined YMRS score ≥5 as a "hypomanic state" in accord with the recommendations of the ISBD (Tohen et al. 2009), the definition and threshold YMRS of previous studies varied and were inconsistent because of insufficient consensus concerning the definition of remission in BD. Therefore, we explored the impact of different cutoff YMRS thresholds on the findings. Our results indicated that different cutoff value of the YMRS score (YMRS score ≥6 versus <6) were also significantly associated with average LAN exposure. Fourth, our primary analysis did not exclude patients with other psychiatric disorders, neurological disorders, and pregnancy. However, the results of additional analysis excluding participants with psychiatric comorbidity were consistent with those in the primary analysis. Fifth, LAN exposure was assessed only by measuring light intensity, not wavelength, by a photometer positioned at eye level. Previous experimental studies have reported that the circadian time structure is not affected by longer light wavelengths (red, orange, or yellow–green), but only by shorter wavelengths (blue and blue–green) (Brainard et al. 2001; Thapan et al. 2001). Another previous study demonstrated that wearing glasses that block blue wavelengths was effective for acute manic symptoms (Henriksen et al. 2016). Therefore, future studies measuring wavelengths could reveal a more appropriate association between LAN exposure and mania. In addition, we had no data on light exposure if the participant left the bedroom at night, such as to visit the bathroom. Moreover, although light data sensed by the wrist actigraphy were recorded 24 h/day for 7 consecutive days, such sleep-time data were excluded from the analysis, because they were considered to contain several artifacts caused by clothing or bedding covering the light sensor of the actigraph. Therefore, our analysis relied only on LAN intensity measured by the photometer in the bedroom from bedtime to rising time. A previous study demonstrated that patients in a manic state had a higher proportion of nocturnal activity measured by actigraphy than that of patients in an euthymic state (Salvatore et al. 2008). Therefore, the participants in the hypomanic state group may have been exposed to more LAN than reflected by the measured results. Moreover, the source of the light could not be distinguished, such as bedroom light or outdoor light entering the bedroom. Furthermore, LAN exposure was only measured for 7 days, so the average LAN intensity over the 7 days may not be the accurate representative value for that period. However, the night-to-night correlations of LAN exposure over 7 days were moderately high, which suggests that the average LAN intensity may be acceptable as the representative value for 7 days. Finally, although we demonstrated that the association between LAN exposure and manic symptoms was independent of several potential confounding factors, we did not investigate other potential confounding factors such as features of BD (e.g., predominant polarity, bipolar cycle, and number of affective episodes), psychological factors, environmental factors (e.g., weather and noise at night), and pharmacological treatment. In addition, the present study lacked a control group.

In conclusion, the study results demonstrated that LAN exposure was significantly associated with manic symptoms in BD patients. This finding may have potential benefit for non-pharmacological intervention and personalized treatment of BD in the future. Further investigation is necessary to confirm the association between LAN exposure and bipolar mania.

Edited by Donald W. Pfaff, The Rockefeller University, New York, NY, and approved November 9, 2010 (received for review August 31, 2010)

Dopamine (DA) is considered crucial for the rewarding effects of drugs of abuse, but its role in addiction is much less clear. This review focuses on studies that used PET to characterize the brain DA system in addicted subjects. These studies have corroborated in humans the relevance of drug-induced fast DA increases in striatum [including nucleus accumbens (NAc)] in their rewarding effects but have unexpectedly shown that in addicted subjects, drug-induced DA increases (as well as their subjective reinforcing effects) are markedly blunted compared with controls. In contrast, addicted subjects show significant DA increases in striatum in response to drug-conditioned cues that are associated with self-reports of drug craving and appear to be of a greater magnitude than the DA responses to the drug. We postulate that the discrepancy between the expectation for the drug effects (conditioned responses) and the blunted pharmacological effects maintains drug taking in an attempt to achieve the expected reward. Also, whether tested during early or protracted withdrawal, addicted subjects show lower levels of D2 receptors in striatum (including NAc), which are associated with decreases in baseline activity in frontal brain regions implicated in salience attribution (orbitofrontal cortex) and inhibitory control (anterior cingulate gyrus), whose disruption results in compulsivity and impulsivity. These results point to an imbalance between dopaminergic circuits that underlie reward and conditioning and those that underlie executive function (emotional control and decision making), which we postulate contributes to the compulsive drug use and loss of control in addiction.

prefrontal cortex | dorsal striatum | substance use disorders | stimulant drugs | brain imaging

Drugs of abuse (including alcohol) are inherently rewarding, which is why they are consumed by humans or self-administered by laboratory animals (1). Only a small percentage of individuals exposed to drugs will become addicted, that is, shift from controlled drug use to compulsive drug use with loss of control over intake despite adverse consequences, however (2). Factors that determine who becomes addicted include genetic (50% of risk), developmental (risk is higher in adolescence), and environmental (e.g., drug access, stress) factors (2).

The mesolimbic dopamine (DA) pathway [DA cells in ventral tegmental area (VTA) projecting into nucleus accumbens (NAc)] seems to be crucial for drug reward (1). Other DA pathways [mesostriatal (DA cells in substantia nigra {SN} projecting into dorsal striatum) and mesocortical (DA cells in VTA projecting into frontal cortex)] are now also recognized to contribute to drug reward and addiction (1). The mode of DA cell firing also differently modulates the rewarding and conditioning effects, of drugs (predominantly phasic DA cell firing) vs. the changes in executive function that occur in addiction (predominantly tonic DA cell firing) (3, 4).

This review summarizes studies that used PET to evaluate DA's role in drug reward and addiction. These findings show that addiction affects not only the DA reward circuit but circuits involved with conditioning/habits, motivation, and executive functions (inhibitory control, salience attribution, and decision making). Other neurotransmitters (and neuropeptides) are involved with drug reward (i.e., cannabinoids, opioids) and with the neuroadaptations from repeated drug use (i.e., glutamate, opioids, GABA, corticotropic-releasing factor). These are not discussed here (except for glutamate), but several reviews address them (5, 6).

DA and Acute Drug Reward

All drugs that can lead to addiction increase DA in NAc, which is achieved through their interaction with different molecular targets by the various drug classes (6) (Table 1). In humans, PET studies have shown that several drugs [stimulants (7, 8), nicotine (9), alcohol (10), and marijuana (11)] increase DA in dorsal and ventral striatum (where NAc is located). These studies used a radiotracer that binds to DA D2 receptors (D2Rs) but only when these are not occupied by DA (i.e., [^{11}C]raclopride). By comparing binding after placebo and after the drug, these studies estimate the decreases in D2R availability induced by the drug, which are proportional to DA increases (12). Most studies have reported that participants who display the greatest DA increases with the drug also report the most intense "high" or "euphoria" (reviewed ref. 13).

PET studies have also shown that the speed with which a drug enters and leaves the brain (pharmacokinetic profile) is crucial for its reinforcing effects. Specifically, PET studies of brain pharmacokinetics of drugs labeled with positron emitters show that peak levels in human brain are reached within 10 min after i.v. administration and that this fast drug uptake is associated with the high (13) (Fig. 1). Indeed, for an equivalent level of cocaine reaching the brain (assessed as equivalent level of DA transporter blockade), when cocaine entered the brain rapidly (smoked and i.v. administration), it elicited a more intense high than when it entered the brain more slowly (snorted) (14). This is consistent with preclinical studies showing that the faster the drug's entry into the brain, the stronger are its reinforcing effects (15). This probably reflects the fact that abrupt and large DA increases triggered by drugs mimic the fast and large DA increases associated with phasic DA firing that are associated in the brain with conveying information about reward and saliency (16).

Drug-induced DA increases in NAc occur in nonaddicted as well as addicted subjects, which raises the question of how they relate to addiction.

To start with, there is increasing evidence that DA's role in reinforcement is more complex than just coding for reward per se (hedonic pleasure) and that stimuli that induce fast and large DA increases also trigger conditioned responses and elicit incentive motivation to procure them (17). Through conditioning, a neutral stimulus that is linked with the reinforcer (i.e., natural reinforcer, drug) acquires the ability by

Table 1. Main classes of drugs of abuse, their main molecular targets, and some of the mechanism(s) by which they increase DA in NAc (44)

Drug	Target	Mechanism for DA increases
Stimulant drugs (cocaine, amphetamine, methamphetamine)	DAT	Blocks DAT on the terminals of DA projecting neurons from VTA to NAc (cocaine) or releases DA from the vesicles of DA terminals (methamphetamine, amphetamine)
Opioids (heroin, opioid analgesics)	MOR	Disinhibits VTA DA neurons by inhibiting GABA interneurons that contain MOR in the VTA or directly activates NAc neurons that contain MOR
Nicotine (cigarettes and other tobacco products)	Nicotinic receptors (predominantly $\alpha4\beta2$ subtype)	Directly activates VTA DA neurons by stimulating their nicotine receptors and indirectly activates them by stimulating the nicotine receptors in glutamatergic terminals to VTA DA neurons
Alcohol and inhalants	Multiple targets, including GABA and glutamate receptors	Facilitates GABAergic neurotransmission, which may disinhibit VTA DA neurons from GABA interneurons or may inhibit glutamate terminals that regulate DA release in Nac
Cannabinoids (marihuana)	Cannabinoid CB1 receptors	Regulates dopaminergic signaling through CB1R in NAc neurons and in GABA and glutamate terminals to NAc

DAT, DA transporter; MOR, μ-opioid receptor.

itself to increase DA in striatum (including NAc) in anticipation of the reward, and this is associated with drug seeking (17). In animals trained to expect a natural reinforcer (food) when exposed to a conditioned stimulus (CS), the DA neurons stop responding to the primary reinforcer and, instead, respond to the CS (16). The extent to which a similar process occurs in response to drugs of abuse is unclear, however, because drugs, through their pharmacological actions, can directly activate DA neurons

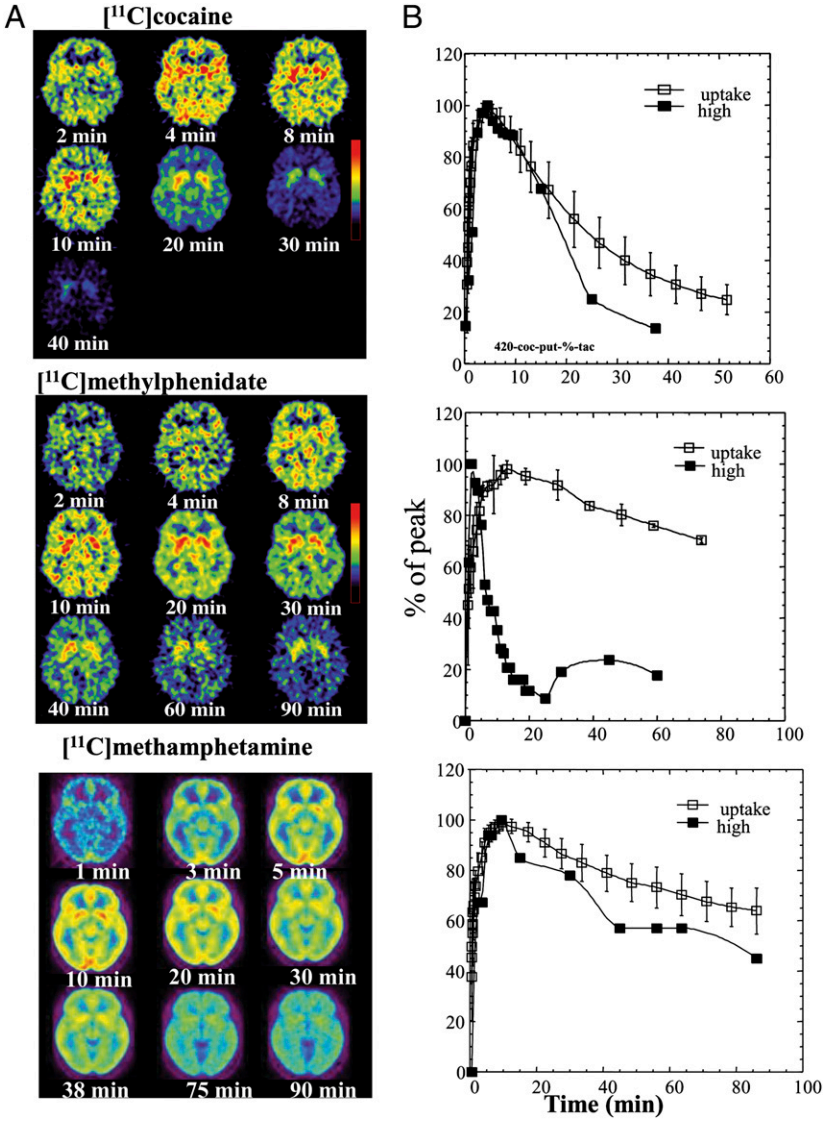

Fig. 1. Pharmacokinetics of stimulant drugs in the human brain and relationship to the "high." (*A*) Axial brain images of the distribution of [^{11}C]cocaine, [^{11}C]MP, and [^{11}C]methamphetamine at different times (minutes) after its administration. (*B*) Time activity curve for the concentration of [^{11}C]cocaine, [^{11}C]MP, and [^{11}C]methamphetamine in striatum alongside the temporal course for the high experienced after i.v. administration of these drugs. Note that the fast brain uptake for these drugs corresponds to the temporal course of the high, which suggests that the high is associated with the "rate of DA increases." In contrast, their clearance shows a correspondence with the high for cocaine and for methamphetamine but not for MP. The difference between MP and cocaine may reflect the differences in their rate of clearance and that between MP and methamphetamine may reflect their different mechanisms of action. Specifically, because MP and cocaine increase DA by blocking DA transporters, the DA increases are terminated by autoreceptor activation, which inhibits DA release. For cocaine, its fast rate of clearance (20-min half-life in brain) results in short-lasting autoreceptor activation, whereas for MP, its slower clearance (60-min half-life) results in long-lasting inhibition of DA release by autoreceptors, which terminates the high even though the drug is still in the brain. In contrast, methamphetamine, which is a DA releaser, is not sensitive to autoreceptor activation; thus, DA increases are not terminated by this mechanism, accounting for the longer lasting duration of the high. (i.e., nicotine) or increase DA release (i.e., amphetamine) (Table 1).

To answer this, we compared DA increases induced by the stimulant drug methylphenidate (MP) between cocaine-addicted subjects and controls. Like cocaine, MP increases DA by blocking DA transporters; both drugs have a similar distribution in human brain and have similar behavioral effects when given i.v. (18). In detoxified cocaine-addicted subjects (n = 20, detoxified 3–6 wk), we showed marked attenuation of MP-induced DA increases in striatum (50% lower) and of the increases in self-reports of high, compared with non–drug-abusing controls (n = 23). Similar findings were reported after administration of i.v. amphetamine (another stimulant drug) in recently detoxified cocaine abusers (detoxified 2 wk), who also showed decreased DA release in striatum and attenuated self-reports of euphoria (19). Because a confound in these studies was the possibility that drug withdrawal accounted for the attenuated DA responses, we repeated this study in active cocaine-addicted subjects (n = 19, nondetoxified) (20). In active cocaine abusers, MP-induced DA changes did not differ from placebo and the DA changes were 80% lower than in controls (n = 24); the self-reports of high were also attenuated (Fig. 2). Marked blunting of striatal DA increases secondary to MP or to amphetamine has also been documented in detoxified alcoholics (reviewed in ref. 13). If, as is currently believed, drug-induced DA increases in NAc underlie drug reward, why would cocaine-addicted subjects, who show a marked attenuation of drug-induced DA increases, compulsively take the drug?

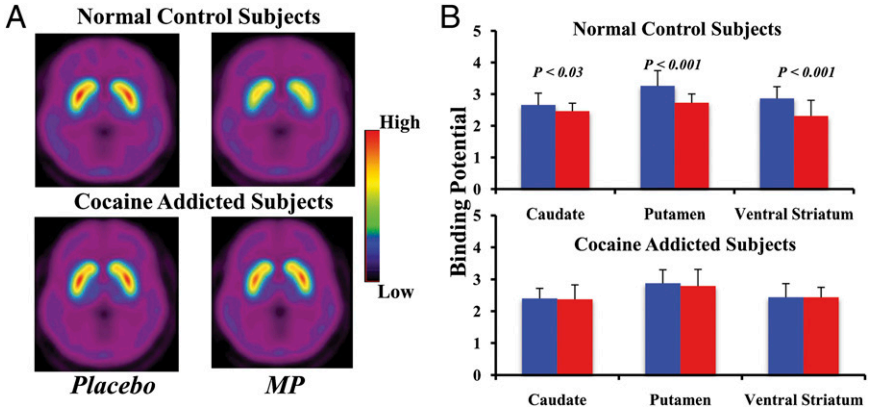

Fig. 2. DA changes induced by i.v. MP in controls and in active cocaine-addicted subjects. (*A*) Average nondisplaceable biding potential (BP_{ND}) images of [^{11}C]raclopride in active cocaine-addicted subjects (n = 19) and in controls (n = 24) tested after placebo and after i.v. MP. (*B*) D2R availability (BP_{ND}) in caudate, putamen, and ventral striatum after placebo (blue) and after MP (red) in controls and in cocaine-addicted subjects. MP reduced D2R in controls but not in cocaine-addicted subjects. Note that cocaine abusers show both decreases in baseline striatal D2R availability (placebo measure) and decreases in DA release when given i.v. MP (measured as decreases in D2R availability from baseline). Although one could question the extent to which the low striatal D2R availability in cocaine-addicted subject limits the ability to detect further decreases from MP, the fact that cocaine-addicted subjects show reductions in D2R availability when exposed to cocaine cues (Fig. 3) indicates that the attenuated effects of MP on [^{11}C] raclopride binding reflect decreased DA release.

DA and Conditioning to Drug Cues

The explanation may arise from the process of conditioning, which is one of the initial neuroadaptations that follow exposure to drugs and involves DA phasic signaling (predominantly D1Rs) and synaptic changes in NMDA and AMPA receptors (modulated by glutamate) (21, 22). These conditioned responses are believed to underlie the intense desire for the drug (craving) and the compulsive use that occurs when addicted subjects are exposed to drug cues.

To assess if drug conditioned cues would increase DA in cocaine-addicted subjects, we tested active cocaine-addicted subjects (n = 18) when subjects watched a neutral video (nature scenes) vs. when they watched a cocaine-cue video (scenes of subjects procuring and smoking cocaine) (23). Cocaine cues significantly increased DA in dorsal striatum, and the magnitude of this increase was correlated with the subjective experience of craving (Fig. 3); similar findings were reported by another laboratory (24). Subjects with the largest cue-induced DA increases in dorsal striatum also had the highest scores on measures of addiction severity. Because the dorsal striatum is implicated in habit learning, this association is likely to reflect the strengthening of habits as chronicity of addiction progresses. This suggests that a basic disruption in addiction might be DA-triggered conditioned responses that result in habits leading to compulsive drug consumption. Inasmuch as in cocaine-addicted subjects, the DA increases triggered by conditioned cues appear to be larger than those produced by a stimulant drug, this suggests that conditioned responses may drive the DA signaling that triggers and maintains the motivation to take the drug. To the extent that the drug (even when its DA-enhancing effects are attenuated) predicts reward, the act of its administration (e.g., injection, smoking) may become a conditioned cue and, as such, may increase DA. Thus, although drugs may initially lead to DA release in striatum (signaling reward), with repeated administration and as habits develop, there appears to be a shift in the DA increases from the drug to the CS, as reported for

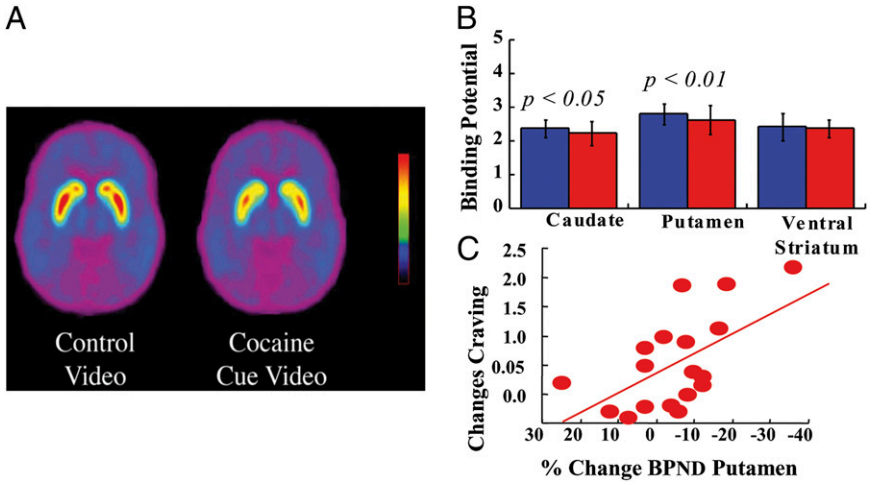

Fig. 3. DA changes induced by conditioned cues in active cocaine-addicted subjects. (*A*) Average nondisplaceable biding potential (BP_{ND}) images of [^{11}C]raclopride in cocaine-addicted subjects (n = 17) tested while viewing a neutral video (nature scenes) and while viewing a cocaine-cues video (subjects administering cocaine). (*B*) D2R availability (BP_{ND}) in caudate, putamen, and ventral striatum for the neutral video (blue) and the cocaine-cues video (red). The cocaine cues decreased D2R in caudate and putamen. (*C*) Correlations between changes in D2R (reflecting DA increases) and self-reports of cocaine craving induced by the cocaine-cues video. Modified from ref. 23.

natural reinforcers (16). Preclinical studies have revealed that glutamatergic projections from prefrontal cortex into VTA/SN and NAc mediate these conditioned responses (5).

DA and Inhibitory Control in Addiction

The capacity to inhibit prepotent responses is likely to contribute to an individual's ability to restrain from taking drugs, and thus his or her vulnerability to addiction (25).

PET studies have shown that addicted subjects have significant reductions in D2R availability in striatum that persist months after protracted detoxification (reviewed in ref. 13). To investigate the functional significance of the striatal D2R reductions, we have assessed their relationship to baseline measures of brain glucose metabolism (marker of brain function). We have shown that reductions in striatal D2R are associated with decreased metabolism in orbitofrontal cortex (OFC), anterior cingulate gyrus (ACC), and dorsolateral prefrontal cortex (DLPFC) (26–28) (Fig. 4). Because OFC, CG, and DLPFC are involved with salience attribution, inhibitory control/emotion regulation, and decision making, we had postulated that their improper regulation by DA in addicted subjects could underlie the enhanced motivational value of drugs in their behavior and loss of control over drug intake (29). In addition, because impairments in OFC and ACC are associated with compulsive behaviors and impulsivity, we postulated that DA's impaired modulation of these regions could underlie the compulsive and impulsive drug intake seen in addiction (30, 31). Indeed, in methamphetamine abusers, low striatal D2R was

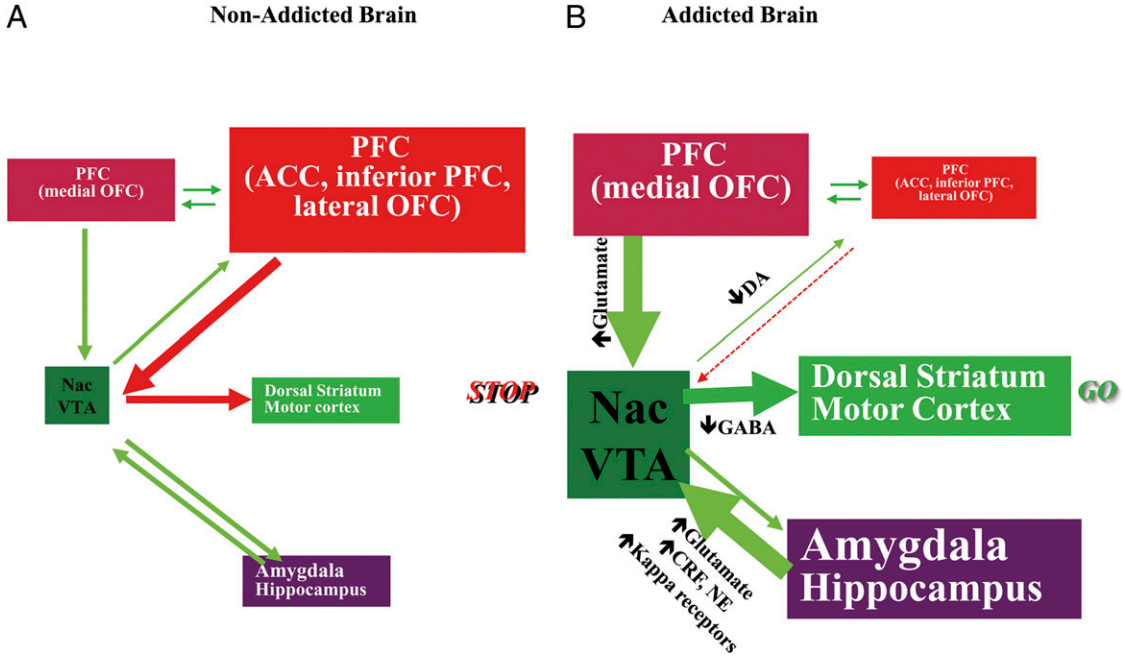

Fig. 5. Model proposing a network of interacting circuits underlying addiction: reward (nucleus accumbens, VTA, and ventral pallidum), conditioning/memory (amygdala, medial OFC for attribution of saliency, hippocampus, and dorsal striatum for habits), executive control (DLPFC, ACC, inferior frontal cortex, and lateral OFC), and motivation/drive (medial OFC for attribution of saliency, ventral ACC, VTA, SN, dorsal striatum, and motor cortex). Nac, nucleus accumbens. (*A*) When these circuits are balanced, this results in proper inhibitory control and decision making. (*B*) During addiction, when the enhanced expectation value of the drug in the reward, motivation, and memory circuits overcomes the control circuit, this favors a positive-feedback loop initiated by the consumption of the drug and perpetuated by the enhanced activation of the motivation/drive and memory circuits. These circuits also interact with circuits involved in mood regulation, including stress reactivity (which involves the amygdala and hypothalamus) and interoception (which involves the insula and ACC and contributes to awareness of craving). Several neurotransmitters are implicated in these neuroadaptations, including glutamate, GABA, norepinephrine, corticotropic-releasing factor, and opioid receptors. CRF, corticotropic-releasing factor; NE, norepinephrine. Modified with permission from ref. 35; permission conveyed through Copyright Clearance Center, Inc.

Downloaded by guest on February 17, 2022

associated with impulsivity (32), and low striatal D2R was associated with impulsivity and predicted compulsive cocaine administration in rodents (33).

It is also possible that the initial vulnerability for drug use occurs in prefrontal regions and that repeated drug use triggers the decreases in striatal D2R. Indeed, in a study done in subjects who, despite having a high risk for alcoholism (positive family history of alcoholism), were not alcoholics, we showed higher than normal striatal D2R availability that was associated with normal metabolism in OFC, ACC, and DLPFC (25). We interpreted this to suggest that normal prefrontal function may have protected these subjects from alcohol abuse.

DA and Motivation in Addiction

DA is also involved in motivation (i.e., vigor, persistence, effort toward the pursuit of reinforcing stimuli) through its regulation of several target regions, including NAc, ACC, OFC, DLPFC, amygdala, dorsal striatum, and ventral pallidum (34).

The enhanced motivation to procure drugs is a hallmark of addiction. Drug-addicted individuals will go to extreme behaviors to obtain drugs, even at the expense of seriously adverse consequences (2). Drug seeking and drug taking become their main motivational drives, which displace other activities (35). Thus, the addicted subject is aroused and motivated when seeking to procure the drug but tends to be withdrawn and apathetic when exposed to non–drug-related activities. This shift has been studied by comparing the brain activation patterns occurring with exposure to conditioned cues with those occurring without such cues.

In contrast to the decreases in prefrontal activity reported in detoxified cocaine abusers when not stimulated with drug or drug cues (reviewed in ref. 13), these prefrontal regions become activated when cocaine abusers are exposed to craving-inducing stimuli (either drugs or cues) (36–39). Similarly, cocaine abusers studied shortly after an episode of cocaine binging showed increased metabolic activity in OFC and ACC (also dorsal striatum) that was associated with craving (40).

Moreover, when we compared the response to i.v. MP between cocaine-addicted and nonaddicted subjects, we showed that MP increased metabolism in ventral ACC and medial OFC (an effect associated with craving) only in addicted subjects, whereas it decreased metabolism in these regions in nonaddicted subjects (41). This suggests that the activation of these prefrontal regions with drug exposure may be specific to addiction and associated with the enhanced desire for the drug. Moreover, in a subsequent study in which we prompted cocaine-addicted subjects to inhibit craving purposefully when exposed to drug cues, we showed that subjects who were successful in inhibiting craving decreased metabolism in medial OFC (processes motivational value of reinforcer) and NAc (predicts reward) (42).

These findings corroborate the involvement of OFC, ACC, and striatum in the enhanced motivation to procure the drug in addiction.

Systems Model of Addiction

As summarized above, several brain circuits are relevant in the neurobiology of addiction. Here, we highlighted four of these circuits: reward/saliency, motivation/drive, conditioning/habits, and inhibitory control/executive function (Fig. 5). The mood regulation circuit (contributes to regulation of stress reactivity) and the interoception circuit (contributes to awareness of drug craving and mood) also participate in addiction, but their involvement in the human brain has been much less investigated. Consequences of the disruption of these circuits are an enhanced motivational value of the drug (secondary to learned associations through conditioning and habits) at the expense of other reinforcers (secondary to decreased sensitivity of the reward circuit) and an impaired ability to inhibit the intentional actions associated with the strong desire to take the drug (secondary to impaired executive function) that result in compulsive drug taking in addiction (35).

Although it is likely that DA changes underlie some aberrant behaviors in addiction, it is also possible that some DA changes may reflect attempts to compensate for deficits in other neurotransmitters, particularly because DA is modulated by glutamate (GABA has been less investigated). Corticostriatal glutamatergic terminals are responsible for learning well-established behaviors and for changing these behaviors when they are no longer adaptive, and neuroadaptations in these projections (and in amygdalostriatal glutamate pathways) with repeated drug use (including impaired regulation of glutamate synaptic release) are implicated in the enhanced motivation for drug seeking that occurs in addiction (5). Impairments in glutamate-induced neuroplasticity with chronic drug exposure are also likely to be involved in the prefrontal function deficits reported in addicted individuals that result in impairments in inhibitory control and in inability to change maladaptive behaviors and to learn from the adverse consequences of drug use.

This model suggests a multipronged therapeutical approach to addiction to decrease the reinforcing properties of drugs, enhance the rewarding properties of natural reinforcers, inhibit conditioned-learned associations, enhance motivation for non–drug-related activities, and strengthen inhibitory control.

Occupation
Creativity

ABSTRACT

Although economists have analyzed earnings, unemployment, and labor force participation for those with bipolar illness, occupational choice has yet to be explored. Psychological and medical studies often suggest an association between bipolar illness and creative achievement, but they tend to focus on eminent figures, case studies, or small samples. We seek to examine occupational creativity of non-eminent individuals with bipolar disorder. We use Epidemiologic Catchment Area data to estimate a multinomial logit model matched to an index of occupational creativity. Those with bipolar illness appear to be disproportionately concentrated in the most creative occupational category. Nonparametric kernel density estimates reveal that the densities of the occupational creativity variable for the bipolar and non-bipolar individuals significantly differ in the ECA data, and suggest that the probability of engaging in creative activities on the job is higher for bipolar than non-bipolar workers.

1. Introduction

The association between creativity and bipolar illness is an age-old controversy.[2] Bipolar illness is characterized by pronounced mood swings—alternating periods of elation, normalcy, and despondency, which can be accompanied by hallucinations or delusions during the peaks and troughs of the cycles. Although we might expect bipolar illness to hamper occupational and artistic achievement, the creativity and energy characteristic of persons with mania may actually improve some aspects of their labor market outcomes (Frank and McGuire, 2000).

Estimates of prevalence of bipolar illness fall around 1.2% of the population (Weissman et al., 1991).[3] With respect to the labor market, the employment of the bipolar population is approximately 71% compared to about 82% for the general population, and those with bipolar illness earn about 57% of the earnings of others, all else equal (Ettner et al., 1997). In contrast to poorer employment and earnings outcomes in the Ettner et al. (1997) study, Marcotte et al. (2000) find that bipolar status in the past year does not significantly affect income or employment for men or women, but that length of time with a bipolar

[2] See Jamison (1993) for a thorough history and literature review of the topic.

[3] This figure is controversial, however. Some psychiatrists claim that bipolar illness is not a discrete phenomenon, but is better characterized as a bipolar spectrum. The fraction of the general population with bipolar spectrum disorder has been estimated at 4.5% in the National Comorbidity Survey Replication (Merikangas et al., 2007) and at 6.4% in the Epidemiological Catchment Area survey (Judd and Akiskal, 2003). At the same time, Zimmerman (2008) find that bipolar disorder is often overdiagnosed by health care professionals. In our work the diagnoses are made based on the National Institute of Mental Health Diagnostic Interview Schedule. There appears to be no difference in the prevalence of bipolar I disorder by sex, race, or ethnicity, and the typical age of onset is 20 years (APA, 2000).

doi:10.1016/j.ehb.2010.01.001

disorder positively and significantly affects employment for women. Further, the lifetime number of bipolar episodes appears to significantly increase income for men. These mixed findings for the bipolar population suggest a need for further study.

None of the economic studies to date have addressed the issue of occupational outcomes for those with bipolar illnesses. Yet there is a substantial body of research on the possible link between creative and artistic occupations and bipolar illness in the medical and behavioral sciences literature. About 75% of these studies find evidence of such a link (Jamison, 1993). Much of this research derives from case studies, biographies of prominent historical figures in the arts, or diagnostic and psychological studies of living writers, artists, and composers. Although rich and informative in their own right, these studies suffer from small sample sizes or from selection bias. In contrast to the case study approach, we employ a population based data set to contribute to the literature on bipolar disorder and creativity as well as the labor market literature on occupational outcomes.

The clinical definition of mania may help in understanding the link between bipolar illness and creativity. Depression characterizes both unipolar and bipolar illness; thus it is an episode of mania that distinguishes bipolar illness (or bipolar I disorder) from unipolar illness. Generally speaking, a manic episode entails "a distinct period of abnormally and persistently elevated, expansive or irritable mood," which may alternate with depressive mood. A manic episode is characterized by at least three of the following symptoms: increased activity, talkativeness, flight of ideas, inflated self-esteem, decreased need for sleep, distractibility, and excessive involvement in risky activities. Some of these symptoms encourage creativity, for example "flight of ideas" and "talkativeness" (which might facilitate rhyming and verse). Increased activity and decreased need for sleep may bolster productivity in a number of occupations.

Another explanation is that there may be a genetic tie between bipolar disorder and creativity. Richards et al. (1988) find that unafflicted close relatives of bipolar patients tend to be more creative than the general population. In addition, Kèri (2009) studied the genomic DNA of 200 healthy, high intellectual achievement individuals, and found that those who carried a genotype related to psychosis risk had the highest creativity levels.[4] Some evolutionary psychologists argue that the positive benefits of creativity might account for the persistence of bipolar disorder in the gene pool in spite of the negative aspects of the illness, although there appears to be some controversy over the reasons for that persistence (Keller and Miller, 2006; Miller and Tal, 2007). It may be that the genetic complexities of mental illness have prevented its elimination by natural selection. For example, individual genes contributing to mental illness may not be harmful alone and may tie to creativity, but when in combination with other genes result in mental illness.

We do not presume to disentangle potential causal factors, but attempt to establish whether or not there is an association between bipolar illness and occupational creativity. Unlike prior studies, we bring a different kind of data, traditional methods from labor economics, as well as nonparametric statistical techniques to bear on this question. Rather than taking a case study approach, we focus on the non-eminent population and use a large population-based sample with automated implementation of the diagnostic criteria to distinguish bipolars from the rest of the sample (the Epidemiologic Catchment Area (ECA) data set).[5] To see if those with and those without bipolar illness have the same occupational outcomes, we use a multinomial logit model of occupational outcomes.

Once differences in occupational outcomes are evaluated, we investigate whether bipolars are concentrated in more creative occupations based on a measure from the *Dictionary of Occupational Titles*. To test for differences in this measure for bipolars we turn to nonparametric methods, since the distribution of the occupational creativity variable is highly skewed, rendering parametric regression analysis inappropriate. Instead we estimate separate nonparametric densities for bipolar and non-bipolar individuals, and test for differences in the distributions.

2. Data and descriptive analysis

The main dataset we utilize is the Epidemiologic Catchment Area Study (ECA), collected by researchers at Yale, Johns Hopkins, Washington, Duke and University of California at Los Angeles in collaboration with the National Institute of Mental Health (NIMH; U.S. Department of Health and Human Services, 1991). Data were obtained by personal interviews of 20,861 adults residing in the towns of these universities: New Haven, Baltimore, St. Louis, Durham and Los Angeles. Respondents were selected using multistage probability sampling. We use the second of two waves of the survey, which was collected in 1981–1985.[6]

To determine if an individual meets the criteria for having a particular mental illness, the ECA interviewers elicited responses to the NIMH Diagnostic Interview Schedule (DIS). Questions are designed to identify symptoms corresponding to criteria in the Diagnostic and Statistical Manual of Mental Disorders, third edition (DSM-III; American Psychiatric Association, 1980). Once the DIS responses are entered into a data file, the DSM-III criteria are operationalized by computer, and diagnoses are

[4] Psychosis refers to the experience of hallucinations and/or delusions (Goodwin and Jamison, 2007: 431; APA, 2000: 414).

[5] We also considered using data from the Mental Health Supplement (MHS) of the National Health Interview Survey. This is also a population-based sample, but with self reported diagnosis of bipolar illness in the last 12 months rather than lifetime as in the ECA. This is a less inclusive definition than that in the ECA sample, as reflected in the small percentage, 0.16, out of 53,441 respondents and more likely to include those with more acute symptoms than in the ECA. We focus instead on the ECA data.

[6] Although the sample is dated, the relationship between bipolar illness and creativity is not likely to change over time. The measure of occupational creativity, discussed below, corresponds to the 1980 occupational codes.

Table 1
Occupational distributions by manic episode status (%).

Occupation	No manic episode	Bipolar (DSM-III)	Bipolar (DSM-III-R)
Professional	20.59	27.38	30.43
Technical	29.54	26.19	21.74
Services	17.27	23.81	26.09
Crafts	10.86	7.14	4.35
Operators	21.73	15.48	17.39
Total percent	100.00	100.00	100.00
Total count	13,570	84	46

Note: Professional includes managerial occupations; technical includes sales and clerical; operators includes fabricators and laborers. DSM-III: Prior episode defined over lifetime. DSM-III-R: Same, but must also have been hospitalized or markedly occupationally impaired. *Source*: Epidemiologic Catchment Area survey, U.S. Department of Health and Human Services (1991), URL: http://dx.doi.org/10.3886/ICPSR08993.

Table 2
Occupational creativity index by occupation.

Occupation	Mean creativity	Standard error	Median creativity	*N*
Professional	10.14	0.40	2.00	2814
Technical	0.95	0.03	0.17	4029
Services	3.47	0.33	0.05	2374
Crafts	0.66	0.03	0.05	1482
Operators	0.45	0.04	0.02	2964
F	176.92			
Prob-F	<0.0001			
χ^2			2800	
Prob-χ^2			<0.0001	

Note: Index is from 0 to 100 with 0 the least creative. Professional includes managerial occupations; technical includes sales and clerical; operators includes fabricators and laborers.

generated for mania as well as a number of other mental illnesses. There are 84 individuals (that is, 0.62%) in the sample with information on occupation who have a DSM-III manic episode diagnosis.

We also consider an alternative diagnostic criteria, the 1987 revised version of the DSM-III, abbreviated DSM-III-R. In addition to the mania diagnosis requirements in the DSM-III, the DSM-III-R includes the criterion of hospitalization or marked impairment in occupational functioning or usual social activities. Excluding those who do not meet this severity criterion, reduces the number of individuals with a DSM-III-R manic episode diagnosis to a total of 46 or 0.34% of the sample.[7]

The ECA sample also contains occupational codes. The occupation variable applies to those currently and previously employed.[8] Table 1 lists the percent of observations in each major occupational group by manic episode status for the two forms of bipolar diagnosis in the ECA sample (DSM-III and DSM-III-R). There is a greater representation of those with a bipolar I diagnosis than the rest of the population in the professional and managerial occupations and services based on the sample data. Bipolars are relatively 'overrepresented' in the services. Likelihood ratio chi-squared tests for differences in occupation distributions by manic status show no significant difference. The probability values for the chi-square statistics are 0.15 for DSM-III criteria and 0.11 for DSM-III-R.

The occupational segregation index (Duncan and Duncan Index of Occupational Dissimilarity) corresponding to the numbers in Table 1 is 13.3, indicating that identical occupation distributions for bipolars and those with no history of mania would arise if 13.3% of either group changed occupations for bipolar DSM-IIIs.[9] To put this figure in perspective, note that it equals the value of the occupational segregation index for African and white American women in 1995 (Blau et al., 1998). The estimated occupational segregation index for DSM-III-R bipolars relative to non-bipolars is 18.7%, higher than for the bipolars diagnosed under the less restrictive DSM-III criteria.

To measure creativity for each individual, we use occupation creativity scores from England and Kilbourne (1988) matched to individuals by 3-digit occupation codes.[10] The occupational creativity measure represents the percentage of employees in a particular occupation

[7] There is a more recent diagnostic and statistical manual of mental disorders, the DSM-IV-TR. In this as well as the DSM-III and DSM-III-R, there is a list of factors that can cause "manic-like episodes" such as substance abuse or a medical condition like multiple sclerosis. When these factors precede symptoms of mania, a diagnosis of mania is not made. A primary change in criteria in the DSM-IV-TR, is that it expands and clarifies the list of factors that preclude a manic episode diagnosis to include factors such as medication and antidepressant light therapy treatment. Light therapy is such a recent tool, we do not believe that it is an issue in our data set. The DSM-IV-TR also lists antidepressant medication and electroconvulsive therapy, and although they are not listed in the DSM-III, they are in the DSM-III-R. For other differences in the manic episode criteria for the three manuals, see American Psychiatric Association (1980, 1987, 2000). The list of symptoms of a manic episode is virtually the same for the DSM-III, DSM-III-R, and DSM-IV-TR. To follow up on the medication and substance use issues we examine a model accounting for alcohol and drugs below.

[8] The occupation recorded for those not currently employed is most recent occupation.

[9] The occupational segregation index for bipolar and non-bipolar workers is given by: $D = (1/2)\sum_i |(B_i/B) - (NB_i/NB)|$ where i indexes occupation, B_i is the number of bipolar workers employed in occupation i, B is the number of bipolar workers in all occupations, NB_i is the number of non-bipolar workers employed in occupation i, and NB is the number of non-bipolar workers in all occupations. The value of the index ranges from 0 to 1, with 0 indicating no occupational segregation and 1 indicating complete segregation (Blau et al., 1998).

[10] The occupational creativity variable is derived from a measure of creativity from the Fourth Edition of the Dictionary of Occupational Titles (DOT) produced by the U.S. Department of Labor. The DOT contains extensive job requirement and characteristic information at a highly detailed level of occupation. The creativity variable reported by the DOT takes one of three values for the requirements of each detailed occupation: (−1)—preference for activities of a routine, concrete, organized nature; (0)—neither pole relevant to occupation; (1)—preference for activities of an abstract and creative nature. It is the latter value in which we are interested. The DOT data were merged with Census Bureau data by 3-digit occupational code, and the percentage of workers in the aggregated occupational group requiring a preference for abstract and creative activities was constructed. This is the occupational creativity variable we use here.

who engage in abstract and creative activities and ranges from 0 to 100.[11]

While Table 1 highlights the relationship between occupations and bipolar status, Table 2 focuses on the creativity levels of occupations, regardless of bipolar status. Table 2 shows the means, standard errors, and median values of the occupational creativity index by occupation group for all workers. Professional and managerial occupations have the highest mean and median creativity levels relative to the other occupational groups, and as shown in Table 1, this occupational category employs an 'over-representation' of those with bipolar illness. Further, the professional and managerial occupational group includes all of the 3-digit occupations classified by Filer (1986) as "artistic."[12] In the services, where bipolars are also over-represented (Table 1), the extent of creativity is less clear. Differences in mean creativity levels are highly significant across occupational groups by an F-test (p-value < 0.0001) as well as pairwise t-tests ($p = 0.001$ or better for all pairs). Differences in medians across occupations are also highly significant (p-value < 0.0001 for the Pearson χ^2 test). Thus creativity varies significantly by occupation for all workers, but the distribution of occupations differs, though not significantly, for bipolars and non-bipolars.

Taking a more direct approach, we segment the sample by diagnosis status and compute the occupational creativity index. Table 3 shows that both the mean and median values of the occupational creativity index are higher for bipolar DSM-IIIs and DSM-III-Rs (means = 4.35 and 4.54, medians = 0.46 and 0.38) than for those not so afflicted (mean = 3.07, median = 0.12).[13] The mean and median values of the bipolar and non-bipolar groups are not significantly different from one another, with the exception of the marginally significant difference in medians for DSM-III bipolars and non-bipolars.[14]

Table 3
Occupational creativity index by diagnosis.

	Mean creativity	Standard error	Median creativity	*N*
Diagnosis				
Bipolar (DSM-III)	4.35	1.62 **	0.46 *	84
Bipolar (DSM-III-R)	4.54	2.20 **	0.38	46
Non-bipolar	3.07	0.10	0.12	13,888

* Significantly different from the non-bipolar group at 10% by Fisher's exact two-sided test and Pearson χ^2 test.

** Variance of creativity variable significantly different from non-bipolar group at 5% or better.

We explore one other measure of creativity from the psychology and career counseling literature: the Holland Artistic (A) Occupational Code (Gottfredson and Holland, 1996).[15] We merged the Holland codes to our sample by 3-digit occupational code, and we used the DSM-III criteria to distinguish bipolars from others in the merged sample. We find that the percent of individuals who are in occupations with an Artistic component is greater for the bipolar group, 10.71 percent, than for the non-bipolar group, 8.40 percent. The difference is not statistically significant which is likely due to the small sample of bipolar individuals, 75 in the non-artistic occupations and only 9 in the artistic occupations.[16]

Interestingly, the variances of the creativity index differ significantly for the non-bipolar group and each of the bipolar groups (p-value = 0.010 for DSM-III and 0.044 for DSM-III-R by a variance ratio F-test). It might be possible that the variability in the expression of the illness across individuals—for example, the length and frequency of episodes, the severity of mania, depression and psychosis, the extent of impairment—results in a greater variance in occupational creativity than among the rest of the population.

In the next section we turn to traditional empirical models to analyze occupational choice. Specifically we use multinomial logit estimation of occupational choice to

[11] Examples of abstract and creative activities include: painting, hairstyling, writing, music teaching, interpreting public opinion surveys in light of contemporary society, creating dramatic stage lighting, planning advertising campaigns, and diagnosing illness (U.S. Department of Labor, 1972).

[12] These include actors and directors; authors; dancers; designers working in the theater, motion pictures, or art museums; musicians and composers; painters, sculptors, craft artists, and artistic printmakers; photographers; postsecondary teachers of art, drama and music; and artists, performers and related workers not elsewhere classified.

[13] The large differences between mean and median values of the creativity index reflect the highly skewed distribution of this variable, which we address below with nonparametric methods.

[14] Fisher's exact two-sided p-value = 0.080 and the p-value for the Pearson $\chi^2 = 0.076$ for the difference in medians for DSM-III bipolars and non-bipolars. p-Values for differences in means for those who are not bipolar relative to either bipolar group are p-value = 0.22 for DSM-III and 0.25 for DSM-III-R diagnoses for one-tailed t-tests with unequal variances. The difference in medians for the 46 persons diagnosed by DSM-III-R criteria and others is not significant by either the Fisher or the Pearson tests ($p = 0.363$ and $p = 0.379$, respectively). We also conduct a Wilcoxon rank-sum (Mann–Whitney) test and obtain insignificant test statistics (p-value = 0.217 for the DSM-III and p-value 0.5844 for the DSM-III-R group). Nonparametric estimation is further discussed below.

[15] According to Gottfredson and Holland (p. 2), the Artistic occupational environment "requires innovation or creative ability. It rewards the display of imagination in artistic, literary, or musical accomplishments, and allows the expression of unconventional ideas or manners. Occupations classified as Artistic generally involve creative work in the arts: music, writing, performance, sculpture, or other relatively unstructured and intellectual endeavors." The Holland model classifies five additional occupational environments: Realistic (R, e.g. carpenter or truck operator), Investigative (I, e.g. psychologist or microbiologist), Social (S, e.g. counselor or clergy member), Enterprising (E, e.g. lawyer or retail store manager), and Conventional (C, e.g. production editor, bookkeeper). For seven different occupational coding systems, Gottfredson and Holland assign three of the six categories, in descending order of importance, to each occupation. For example, the code for economists is ISA, investigative rated most important, followed by social (which includes teaching, mentoring and concern for the welfare of others), and then artistic (likely for the creativity and innovation features). The statistics referred to above apply to all occupations that have an Artistic component (i.e., Axx, xAx, or xxA where x = R, I, S, E, C).

[16] The p-values for a one-tailed t-test, a Pearson χ^2 test, and a Fisher exact test are 0.2226, 0.5537 and 0.2733, respectively. We include the p-value for the t-test because it is so commonly used. The t-test is not technically appropriate in this case, however, because the variable, percent of individuals who are in occupations with an Artistic component, derives from a set of discrete variables and is not normally distributed.

Table 4
Multinomial logit marginal effect estimates of bipolar status on occupational outcomes.

	Professional	Technical	Services	Crafts	Operators	*N*	LR
Base model, full sample							
Bipolar (DSM-III)	0.05 (0.96)	−0.05 (0.97)	**0.09** (1.75)	−0.03 (1.12)	−0.07 (1.49)	13,622	3235
Bipolar (DSM-III-R)	0.08 (1.16)	**−0.11** (1.76)	0.11 (1.49)	**−0.05** (1.69)	−0.04 (0.58)	13,584	3216
Full sample, controlling for alcohol and drugs							
Bipolar (DSM-III)	0.07 (1.43)	−0.04 (0.77)	0.07 (1.60)	−0.03 (1.24)	**−0.07** (1.84)	13,622	3378
Bipolar (DSM-III-R)	**0.11** (1.68)	−0.09 (1.51)	0.08 (1.32)	**−0.06** (1.77)	−0.05 (0.88)	13,584	3265

Note: Base model does not control for alcohol/drugs, marital status or education. Professional includes managerial occupations; technical includes sales and clerical; operators includes fabricators and laborers. Absolute values of *t*-ratios are in parentheses. N = number of observations. LR = likelihood ratio; all LR values are significant at 1%. Coefficients in bold are significant at 10%.

determine if bipolar status significantly affects occupational choice. We then return to analyzing the relationship between bipolar illness and the occupational creativity index. We use nonparametric techniques to estimate kernel densities of the occupational creativity index for bipolars and non-bipolars and test for differences in the distributions.

3. Results of multivariate analysis

3.1. Multinomial logit occupation regressions

We estimate a multinomial logit model of the probability of employment in each occupational group as a function of manic episode status. Control variables in the base model include RACE = 1 if individual i is African-American (= 0 otherwise), FEM = 1 if i is female (= 0 otherwise), and AGE. Sets of dummy variables for year of interview and interview site are also included. Although it might be desirable to include education level in the regression, it was not collected at Johns Hopkins or Washington University. For the set of remaining observations from the Yale, Duke, and UCLA communities, the mean education level is significantly higher for bipolar I's than for the rest of the sample at 1 percent or better (12.77 compared to 11.52 for the DSM-III group and 12.97 versus 11.52 for the DSM-III-R group). Since the sample is limited, results controlling for education are discussed below with alternate specifications.

Multinomial logit estimates of marginal effects of the bipolar dummy variable for alternative occupation groups are presented in Table 4. These include results for the full sample with the base model (no education, no marital status, no alcohol or drug variables included). The results show that the marginal effect of the bipolar dummy variable for a manic episode is positive across the board in the most 'creative' occupations: professional and managerial and services, although the marginal effects are significant at the 10 percent or better level in only one case: DSM-III for services. The marginal effect is consistently negative for the other 'low creativity' occupations, and is significant at 10 percent in two cases in the base model: for technical, sales and clerical and for crafts for DSM-III-R in both cases.

Recall that in contrast to the DSM-III diagnosis of bipolar illness, DSM-III-R requires hospitalization or marked impairment in occupational functioning or usual social activities, which reduces the number of individuals classified as bipolar in the sample to 46. Note that if we wish to investigate the relationship between bipolar illness and occupational creativity, and if occupational impairment is used as a criterion for bipolar illness, we might expect to understate occupational creativity for the DSM-III-R classification. However, when the DSM-III variable is replaced by the DSM-III-R dummy variable for a mania diagnosis in the logit model, we see an increase in the absolute value of the bipolar marginal effect[17] suggesting even stronger selection of bipolars into relatively creative occupations.

The occupational impairment rule in the DSM-III-R diagnostic criteria has identified bipolars as more frequently employed in creative occupations with a higher mean (but lower median) level of occupational creativity, a greater degree of occupational segregation relative to the well, and somewhat stronger multinomial logit evidence linking the presence of the disease to creative occupations than the bipolars identified under the DSM-III rules. Thus, even with the potential bias this new screen may impose, there appears to be some evidence of a link between occupational outcomes, creativity and bipolar disorder.

3.2. Alternative specifications

We estimate a number of alternative specifications, and the substantive results are unchanged. We add a marital status dummy variable and then an education variable to the set of demographic variables in the base model. Although we do not report them here, (results available on request), the signs of the estimated marginal effects on the bipolar dummy variables are robust to these specification changes. For both full sample and 3-site sample, and both DSM-III and DSM-III-R criteria, the signs are the same as in the base model: positive for the professional and managerial occupations, negative for the technical, sales and clerical jobs; positive for the service jobs; negative for the crafts; and negative for the operators, fabricators and laborers.

We next consider another set of specifications which control for co-morbid psychiatric illnesses. Each model includes a dummy variable for schizophrenia, obsessive-compulsive disorder, phobia, panic disorder, anti-social personality or alcohol and drug abuse.[18] The signs on the

[17] With the exception of the operators category.
[18] Due to small sample sizes, only one co-morbid psychiatric illness can be represented in the model at a time.

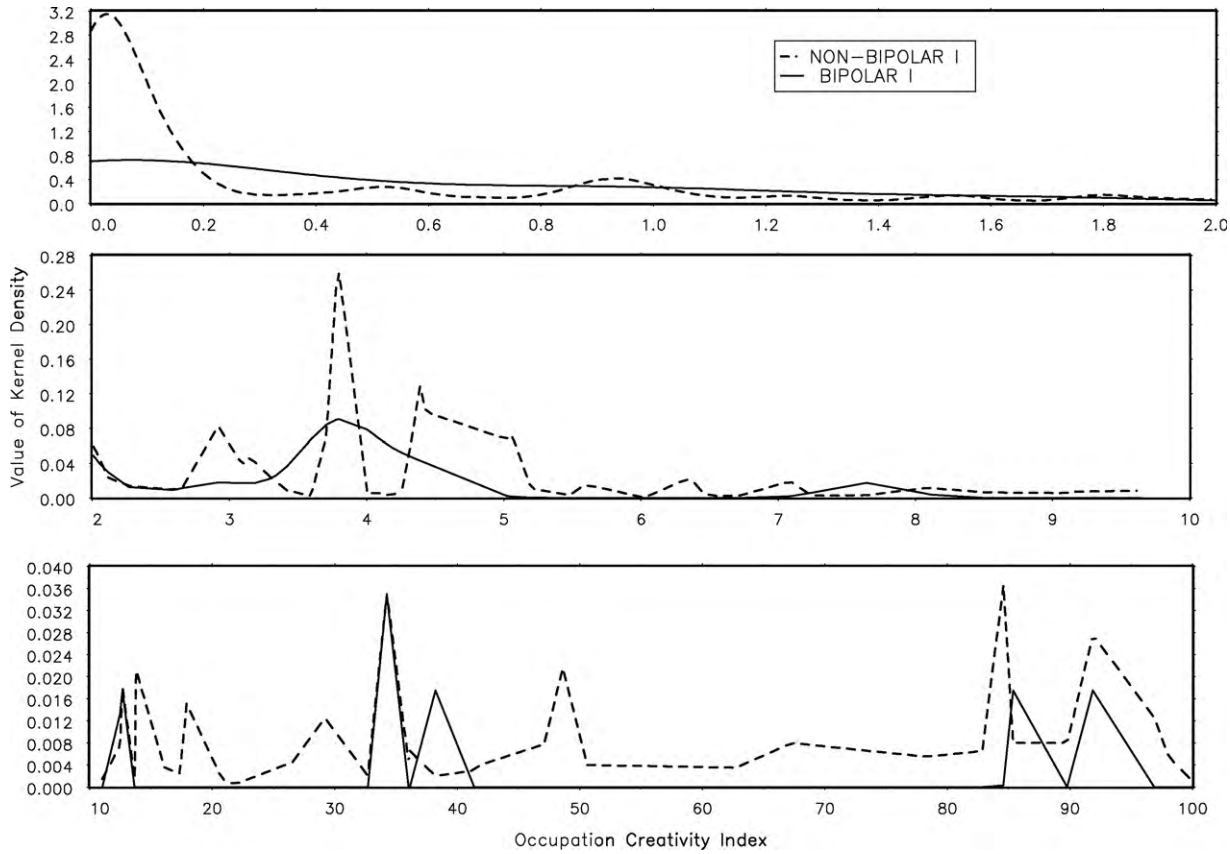

Fig. 1. Kernel density of the occupational creativity index with Silverman's bandwidth. *Note*: The value of 100 for the occupational creativity index indicates the highest level of creativity. The bandwidth selection method is from Silverman (1986).

marginal effects of bipolar illness do not change from the original base models.

The lower panel of Table 4 shows the results of the model that accounts for alcohol or drug abuse. Specifically, this model includes ALCDRGS, a dummy variable = 1 if the individual has a diagnosis of alcohol dependence and/or abuse, or drug dependence and/or abuse. The marginal effect estimates of manic episode status are similar in value as for the base model in the upper panel. Note that statistical significance on the marginal effect of the bipolar dummy is lost for the technical group (DSM-III-R) but gained for the operators group (DSM-III). For the 'creative' occupational categories, the estimate for the DSM-III bipolar dummy variable loses significance for services, but the estimate for the DSM-III-R bipolar variable gains significance at 10 percent for the professional and managerial group.

In summary, we have explored a number of alterations to the base model, and we find that the estimated marginal effects of bipolar illness are remarkably consistent across specifications. In particular, the influence of bipolar status on the probability of being in a professional and managerial occupation or a service occupation is uniformly positive. Next we turn to some additional evidence based on nonparametric tests and estimation.

3.3. Nonparametric evidence

Recall that we found large differences between the mean and median values of the occupational creativity index (Table 3) for bipolars and non-bipolars. Consequently, we turn to nonparametric tests and estimation techniques to address these distributional issues.

We first estimate Kolmogorov–Smirnov test statistics for the equality of occupational creativity distributions for bipolar and other individuals, and find corrected p-values of 0.103 for the DSM-III group and 0.519 for the DSM-II-R group. It is surprising that the p-values are not lower, based on our earlier results on the significant differences in the variances of the creativity index for bipolars and the rest of the sample for both DSM-III and DSM-III-R subsamples. We now use nonparametric kernel density estimation to further explore and test for differences in the occupational creativity index distribution for bipolars and other individuals.

3.3.1. Nonparametric density estimation

The advantage of nonparametric density estimation is that it is flexible and nonrestrictive. It can reveal the underlying density of a variable, even when that density deviates from the traditional normal form often assumed in parametric estimation. As the particular density of a

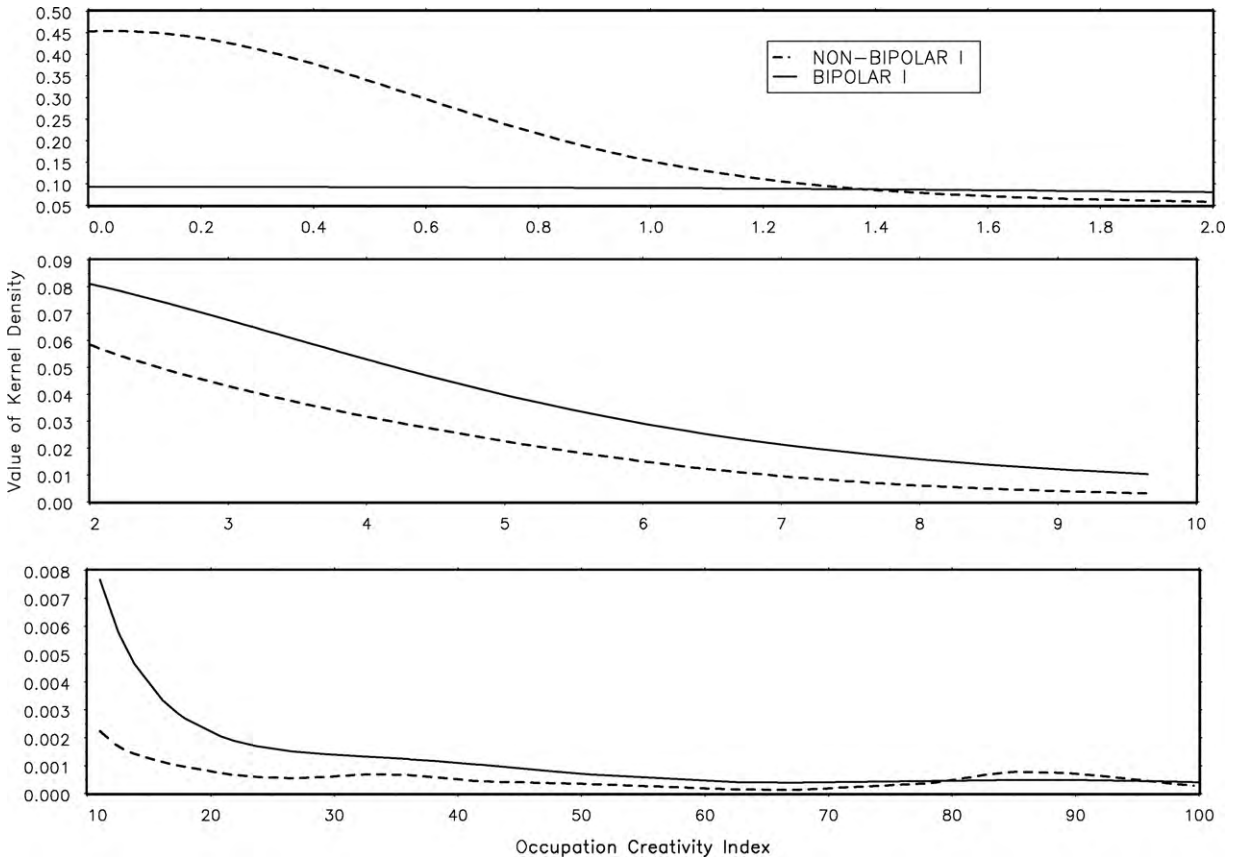

Fig. 2. Kernel density of the occupational creativity index with adaptive bandwidth.

variable need not be assumed a priori, specification errors can be avoided.

Here we estimate nonparametric kernel densities for the occupational creativity index for the bipolar and non-bipolar groups. For the kernel, we choose the Gaussian (standard normal) density function. The more difficult issue is the choice of bandwidth. We begin with the automatic bandwidth choice method described in Silverman (1986), which minimizes the integrated squared error (ISE) between the estimated function and the objective function. The kernel estimates using Silverman's plug-in bandwidth are displayed in Fig. 1.[19] The estimated densities are segmented into three intervals: [0,2) in the upper panel, [2,10) in the middle panel, and [10,100] in the lower panel. The upper panel highlights the heavy concentration of the data near zero, indicating that many workers do not perform creative activities in their jobs. The density is far less concentrated near zero for bipolar than for non-bipolar workers, however, evidence of greater occupational creativity for bipolars than non-bipolars. Note that the values of the kernel densities on the *y*-axis in the three panels dramatically decline from the upper to the middle to the lower panels. This reflects the skewness and lengthy tails of the distributions. Although Silverman's bandwidth produced a smooth density for values of the occupational creativity variable less than 2, the lower panels show that from 2 and beyond, the tails of both kernel densities are undersmoothed.

To focus on the tail distributions without oversmoothing the rest of the distribution, we employ another bandwidth selection method known as the 'adaptive two stage estimator' (A2SE), first considered by Breiman et al. (1977) and Abramson (1982). The basic idea is to use a broader bandwidth in the regions of low density to smooth the tail part of the function. Our results using this method are displayed in Fig. 2. Again we separate the kernel density into the intervals, [0,2), [2,10) and [10,100].[20] It is clear from the upper panel that the non-bipolar population is more concentrated at the lowest creativity levels. Over the 2–10 and 10–80 ranges of the creativity index, the bipolar population has higher density. By inspection, the

[19] Silverman's plug-in bandwidth is calculated as $h = 0.79RN^2$ where R is the inter-quartile range of the data and N is the sample size.

[20] The range of numbers on the *y*-axes in Fig. 1 differs from that in Fig. 2 because Silverman's bandwidth is much smaller than the A2SE bandwidth, on average. The area under a kernel density plot is one by design. With a larger bandwidth (A2SE), the weight of the density is allocated more evenly over the values of the creativity index in order to get a smoother curve, whereas with a smaller bandwidth (Silverman's) the weight is concentrated near the origin where most of the data points are located.

Table 5
Occupation creativity index dist. (c) by bipolar status.

Probability	Bipolar	Non-bipolar
$P(c \geq 1)$	0.3095	0.2599
$P(c \geq 2)$	0.1786	0.1627
$P(c \geq 3)$	0.1667	0.1424
$P(c \geq 4)$	0.1071	0.0922
$P(c \geq 5)$	0.0833	0.0724
$P(c \geq 6)$	0.0833	0.0576
$P(c \geq 7)$	0.0833	0.0531
$P(c \geq 8)$	0.0714	0.0495
$P(c \geq 7)$	0.0714	0.0466
$P(c \geq 8)$	0.0714	0.0441

Note: the highest value of c is 100.

area between the two densities from 10 to 80 (and about 95 to 100) exceeds the area from 80 to 95 where the bipolar density lies below the non-bipolar density. We also calculate the probabilities of observing the occupational creativity index above various values (integers 1 through 10) for each group. These are displayed in Table 5. The median level of the occupational creativity index (c) lies between 0.12 and 0.46 for the non-bipolar and bipolar samples, respectively (Table 3). The probability that c is greater than or equal to one in column (1) represents part of the "tail" above the median. We see that the probability of observing an occupational creativity index greater than one is higher for bipolars than non-bipolars (0.31 versus 0.26). The probability is higher for bipolars for every value of the creativity index up to greater than or equal to 10, which represents 4–7 percent of the samples.

To test if these densities are significantly different, we follow the method proposed by Li (1996). Let the two densities be $f(x)$ and $g(x)$, then test the null hypothesis $H_o : f(x) = g(x)$ against $H_1 : f(x) \neq g(x)$. The idea is to construct a nonparametric approximation for the integrated squared difference between the two estimated functions, i.e., the test statistic is based on $I = \int (\hat{f} - \hat{g})^2$. For our sample, the estimated test statistic is $Z = -3.01$ with a p-value of 0.001, so $H_o : f(x) = g(x)$, that the density functions of the occupational creativity index for non-bipolars and bipolars is the same, is rejected. That is, the densities are highly significantly different. This provides evidence of creativity differences for bipolar and non-bipolar persons.

4. Conclusion

Earlier work investigating links between occupational creativity and bipolar illness is largely based on psychiatric case studies or very small samples. In contrast we use a population based data set and econometric techniques to analyze occupational outcomes for those with bipolar disorder and the general population. We find evidence that bipolars are concentrated in service occupations as well as in professional and managerial occupations. We match the occupations to a measure of occupational creativity from the *Dictionary of Occupational Titles*. The professional and managerial occupations which include artists, musicians, and authors, are the most creative occupational category based on this index. We also find significantly higher median occupational creativity (DSM-III group) and education levels (both groups) for bipolars than for the general population.

After establishing the connection between occupation and creativity, we investigate the occupational outcomes of bipolars versus others in our sample using multinomial logit regressions. The results show that the effect of the bipolar dummy variable for a manic episode is positive in the most creative occupations: (1) professional and managerial, and (2) services. This result is robust to a number of alternative specifications.

We employ nonparametric density estimation methods to compare the densities of the occupational creativity index for the bipolar and non-bipolar samples. Based on these estimates we reject the null hypothesis that the densities are the same for bipolar I's and non-bipolars at the 0.1% level of significance. Probabilities based on these estimates also suggest that the data are more likely to reside in the tail of the creativity index density for bipolar than non-bipolar workers. That is, the probability of engaging in creative activities on the job is higher for bipolar than non-bipolar workers.

Still a number of caveats are in order. Some of the hypothesis tests here resulted in insignificant or marginally significant test statistics. Longitudinal data would better reveal the time patterns of illness onset, education, marital states and career paths. Selectivity issues, such as observing creativity of only employed or previously employed bipolar individuals, with longitudinal data as well. Future studies would also benefit from more recent data including the current diagnostic criteria (DSM-IV-TR).

Nevertheless we do find substantive evidence of a link between bipolar illness and occupational creativity using quite different data and methods than previous studies. This implies that productivity gains from enhanced creativity might outweigh productivity losses resulting from bipolar illness (for example, from absenteeism and lack of energy during depressive states). Thus, employers might be more willing to comply with the Americans with Disabilities Act of 1990, which prohibits discrimination against qualified persons on the basis of disability, including bipolar disorder, in all employment practices, and mandates employer provision of accommodations, such as modified work schedules and job reassignment, to enable performance of essential job functions.[21] Understanding their potential contributions might encourage employers to more readily hire and facilitate the productive capacities of individuals with bipolar illness.

The extent to which bipolar persons contribute to the stock of creative human capital in the workforce has implications for society's response to the inevitable identification and understanding of the genetic markers for bipolar disorder. The creative benefits of the disease is one factor weighing against its elimination via genetic

engineering or selective abortion (Goodwin and Jamison, 2007: 405–406, 461). The development of medication that reduces the social and private costs of the illness without inhibiting creativity might be a fruitful social investment.

Summary

Memory consolidation is a dynamic process. Reactivation of consolidated memories triggers reconsolidation, a time-limited period during which memories can be modified [1–4]. Episodic memory refers to our ability to recall specific past events about what happened, including where and when [5]. However, it is unknown whether noninvasive stimulation of the neocortex during reconsolidation might strengthen existing episodic memories in humans. To modify these memories, we applied repetitive transcranial magnetic stimulation (rTMS) [6] over right lateral prefrontal cortex (PFC), a region involved in the reactivation of episodic memories [7, 8]. We report that rTMS of PFC after memory reactivation strengthened verbal episodic memories, an effect documented by improved recall 24 hr postreactivation compared to stimulation of PFC without reactivation and vertex (control site) after reactivation. In contrast, there was no effect of stimulation 1 hr postreactivation (control experiment), showing that memory strengthening is time dependent, consistent with the reconsolidation theory. Thus, we demonstrated that right lateral PFC plays a causal role in strengthening of episodic memories through reconsolidation in humans. Reconsolidation may serve as an opportunity to modify existing memories with noninvasive stimulation of a critical brain region, an issue of fundamental importance for memory research and clinical applications.

Results and Discussion

Consolidation theory assumes that memories are unstable (i.e., susceptible to interference) for a limited time after encoding, but as time passes, memories stabilize and become resistant to interference [9]. Newly formed memories require gene expression for several hours in order to become stable or consolidated [3]. However, studies done in the last decade demonstrated that the initial gene-expression-dependent phase is not the only one [1–3]. In fact, consolidated memories can re-enter unstable states when they are reactivated during retrieval or by a reminder cue and need to consolidate again in order to persist over longer periods of time [1–4]. Thus, the concept of reconsolidation assumes that memories are not consolidated once and forever, challenging the view that stability characterizes consolidated memories [2–4]. Indeed, memory reactivation triggers reconsolidation, a time-limited period during which existing memories are susceptible to modifications [1–4]. Thus, memories can be stabilized, strengthened [10–13], weakened/disrupted [1, 14, 15], or updated by the inclusion of new information [16, 17] through reconsolidation.

Episodic memory refers to our ability to recall specific details about past events, including where, when, and what happened [5]. The prefrontal cortex (PFC) is a critical node in the neural network mediating the encoding and retrieval of these memories [7, 18].

Although previous human studies on reconsolidation have shown that existing episodic memories can be enhanced by stressor events [10], emotional processing [11], successive reactivations of the memories [12], or pharmacological modulations [13], it remains unknown whether the lateral PFC plays a causal role in the reconsolidation process.

To modify episodic memories, we applied repetitive transcranial magnetic stimulation (rTMS) over right lateral PFC. Since retrieval or reactivation by a reminder cue triggers reconsolidation, we decided to stimulate a neocortical region involved in retrieval [7, 18] and reactivation of episodic memories [8]. Previous rTMS studies demonstrated the causal role of right, but not left, lateral PFC in retrieval [7, 18], and these findings were confirmed in a functional resonance magnetic imaging (fMRI) study showing activation of the right, but not left, lateral PFC during memory reactivation by a reminder cue [8]. rTMS is a noninvasive brain stimulation technique used in this protocol to evaluate the causal role of focal neocortical regions and to modulate cognitive function [6, 19] (see the Supplemental Experimental Procedures available online).

Subjects (n = 30) learned a list of 20 object words on day 1. This procedure was repeated until the participants remembered at least 17 of the 20 words (85%) or until a maximum of four learning trials was reached [16, 17]. On day 2, in a subset of subjects (n = 10), existing memories were reactivated by a spatial-contextual reminder cue (without explicit recall), and 10 min later 1 Hz rTMS was applied for 15 min to right dorsolateral PFC (PFC-R) (see the Supplemental Experimental Procedures). There is evidence that memories are automatically reactivated if the original learning spatial context is part of the reminder [17]. To determine whether the rTMS effect was specific to memory reactivation and relied on right PFC function, we designed two control conditions that were applied to the remaining subjects (n = 10 per group). First, to determine whether the rTMS effect was specific to memory reactivation, we applied rTMS over right PFC without memory reactivation (PFC-NR), a behavioral manipulation previously successfully done in animal [1] and human [16] reconsolidation studies. Second, to determine whether the rTMS effect was topographically specific, we applied rTMS over the vertex after memory reactivation (vertex-R, control site) [6]. We chose the frequency of rTMS on the basis of a recent study showing that 1 Hz rTMS of right lateral PFC enhanced episodic memory performance when delivered during the interval (10 min) between encoding and retrieval [20]. Memory recall was tested on Day 3 (24 hr postreactivation) (see Figure 1 and the Supplemental Experimental Procedures).

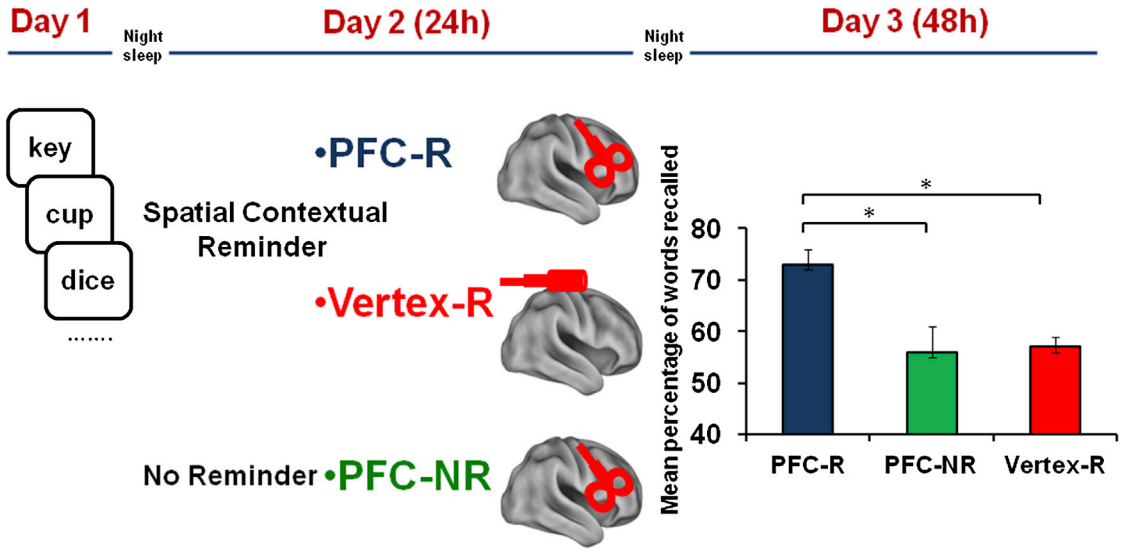

Figure 1. Timeline and Results of Experiment 1

Subjects learned 20 words on day 1. On day 2, rTMS was applied to right dorsolateral PFC (PFC-R) or a control site (vertex-R) after memory reactivation by a spatial-contextual reminder. A third group of subjects received rTMS of right PFC without memory reactivation (PFC-NR). Recall was tested on day 3. The plot shows the mean percentage of words recalled in each group (n = 10). Error bars represent the SEM. *p < 0.0167. Cortical surfaces were generated using CARET (http://brainvis.wustl.edu/wiki/index.php/Main_Page).

In order to compare the learning rate of the three experimental groups, we recorded how many learning trials (1–4) were necessary for participants to recall at least 17 words (85%) on day 1. Participants needed on average 3.4 learning trials to reach this criterion (PFC-R = 3.3 ± 0.26 [mean ± SEM]; PFC-NR = 3.5 ± 0.22; vertex-R = 3.4 ± 0.27). There were no significant differences between the three groups (H = 0.133, p = 0.93).

Regarding the number of words recalled on day 3 (see the Supplemental Experimental Procedures), the main effect "group" was significant [F(2,27) = 6.30, p < 0.01]. Independent t tests (Bonferroni corrected, p = 0.0167) showed significant differences between PFC-R (14.3 ± 0.63) and PFC-NR (11.3 ± 1.05) (p < 0.0161) and between PFC-R and vertex-R (11.32 ± 0.45) (p < 0. 0006). No difference was found between PFC-NR and vertex-R (p = 0.9658). To enable comparison between experiments, we have displayed the mean percentage of words recalled in each group in Figure 1 (PFC-R = 73% ± 3.17%; PFC-NR = 56.3% ± 5.24%; vertex-R = 56.6% ± 2.27%).

These findings show that stimulation of right PFC after memory reactivation (PFC-R) strengthened verbal episodic memories, an effect indicated by enhanced later recall (24 hr postreactivation) compared to rTMS of PFC without memory reactivation (PFC-NR) or rTMS of a control site after memory reactivation (vertex-R).

To determine whether the rTMS effect (PFC-R) was reconsolidation specific, we carried out a control experiment (experiment 2). Because reconsolidation is a process requiring gene expression for several hours [2, 3], memory modification should not be expressed shortly postreactivation (i.e., 1 hr, when the memories are still unstable) but many hours later (i.e., 24 hr, after memories have become stable again) [2, 3, 13, 16]. In animal studies, memory reconsolidation is only observed after a delay of about 4 hr [2].

To address this question, in experiment 2 we used exactly the same materials and followed exactly the same procedure as in experiment 1 with one exception: the experiment consisted of only two experimental sessions in consecutive days (24 hr apart). The procedure described for day 3 in experiment 1 (i.e., memory recall) was administered on day 2 shortly (i.e., 30 min) after the end of the rTMS session (1 hr postreactivation). This 30 min interval was chosen to allow the aftereffects of rTMS to wash out in order to avoid effects on the retrieval process per se [6]. Based on the findings of experiment 1, we compared right PFC-R (n = 10) to vertex-R (n = 10) (see Figure 2).

Subjects (n = 20) needed on average three learning trials to recall at least 17 words (85%) (PFC-R = 3 ± 0.30; vertex-R = 3 ± 0.26). No significant differences were found between the groups (U = 48.0, p = 0.87).

Regarding the number of words recalled on day 2 (see the Supplemental Experimental Procedures), the main effect of "group" [F(1,18) = 0.133, p = 0.72; PFC = 13.85 ± 0.95; vertex = 13.4 ± 0.95] was not significant. The mean percentage of words recalled in each group is displayed in Figure 2 (vertex-R = 67% ± 3.94%; PFC-R = 69.25% ± 4.74%).

Figure 2 shows that, in opposition to findings with recall on day 3 (24 hr postreactivation), testing shortly (1 hr) postreactivation on day 2 yielded comparable results for both vertex-R and PFC-R stimulation. These results suggest that the effect of experiment 1 is time dependent because it is only seen if the memory trace is allowed to reconsolidate.

In this study, we show that rTMS of right lateral PFC after memory reactivation (PFC-R) strengthens existing verbal episodic memories in humans, an effect indicated by enhanced later recall (24 hr postreactivation) compared to control groups (i.e., vertex-R and PFC-NR). Moreover, this effect does not occur when memory performance was tested shortly postreactivation (1 hr). Thus, as predicted by reconsolidation theory [2, 3], the effect of rTMS over right lateral PFC evolves over time and depends on memory reconsolidation.

In this study, we demonstrate for the first time that reconsolidation may serve as an opportunity to strengthen existing

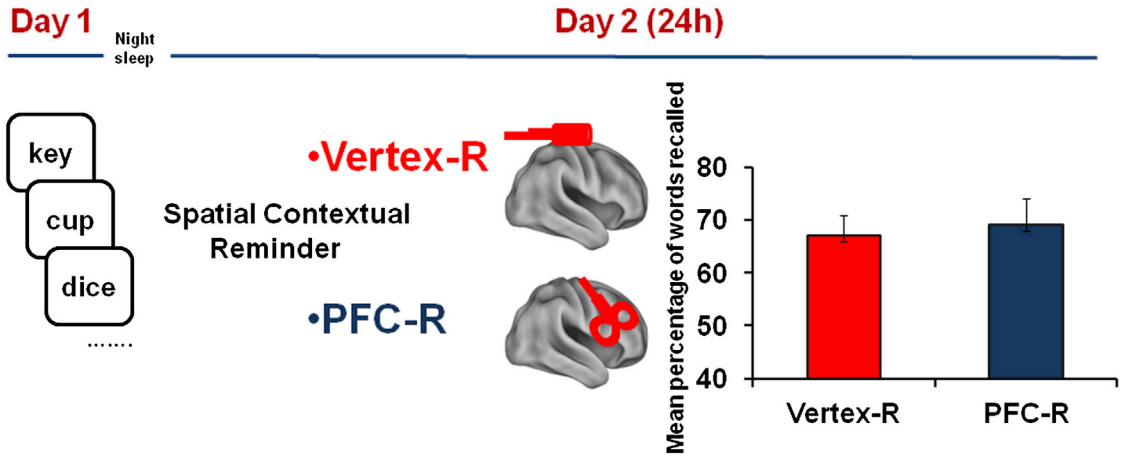

Figure 2. Timeline and Results of Experiment 2

Subjects learned 20 words on day 1. On day 2, rTMS was applied to right dorsolateral PFC (PFC-R) or a control site (vertex-R) after memory reactivation by a spatial-contextual reminder. Recall was tested shortly (30 min) after rTMS. The plot shows the mean percentage of words recalled in each group (n = 10). Error bars represent the SEM. Cortical surfaces were generated using CARET (http://brainvis.wustl.edu/wiki/index.php/Main_Page).

episodic memories with non-invasive stimulation of the right lateral PFC, showing that enhanced recollection can be achieved by targeting a critical brain region during a postreactivation state of plasticity.

Regarding the putative brain mechanisms of this effect, the role played by spatial context in memory reactivation [17] points to hippocampal involvement in this paradigm [4] and suggests possible functional interactions between this brain region and PFC during the reconsolidation process [21]. It is well recognized that memory consolidation involves a relatively brief cascade of molecular and cellular events that alter synaptic efficacy as well as a prolonged systems level interaction between the hippocampus and neocortex [4, 21]. Episodic memories initially consist of two components: content representations dependent on neocortical networks and a spatial-contextual representation dependent on the hippocampus [4], which seems to serve as the memory trace that permits the retrieval of memory content stored elsewhere [22].

Since rTMS affects not only the targeted local region but also activity in remote interconnected regions [6, 19], 1 Hz rTMS of right PFC after memory reactivation may have enhanced the functional coupling between the PFC and the hippocampus, thereby enhancing memory recollection through reconsolidation. There is evidence that 1 Hz rTMS may improve performance of a cognitive task by strengthening the connectivity between task-relevant brain regions depending on the functional state of the cortex at the time of stimulation [23]. Thus, combined TMS-fMRI studies may shed light on how functional interactions between remote but interconnected brain regions may support reconsolidation of episodic memories [6, 19]. Future work might identify the time window of memory reconsolidation by varying the interval between memory reactivation and rTMS and address the question of whether the same or different lateral PFC regions (i.e., left versus right and dorsal versus ventral) operate in both consolidation and reconsolidation.

We conclude that right lateral PFC plays a critical role in the neural network that mediates the strengthening of episodic memories through reconsolidation in humans.

Noninvasive stimulation of a critical brain region during reconsolidation may be a new opportunity for designing well-controlled, double-blinded interventional studies, which can potentially strengthen adaptive memories in elderly adults and individuals with memory dysfunctions (e.g., mild cognitive impairment) or disrupt maladaptive memories in individuals with posttraumatic stress disorder.

Experimental Procedures

The experimental procedures are summarized briefly throughout the Results and are presented in complete detail in the Supplemental Experimental Procedures.

Creative thinking represents a major evolutionary mechanism that greatly contributed to the rapid advancement of the human species. The ability to produce novel and useful ideas, or original thinking, is thought to correlate well with unexpected, synchronous activation of several large-scale, dispersed cortical networks, such as the default network (DN). Despite a vast amount of correlative evidence, a causal link between default network and creativity has yet to be demonstrated. Surgeries for resection of brain tumors that lie in proximity to speech related areas are performed while the patient is awake to map the exposed cortical surface for language functions. Such operations provide a unique opportunity to explore human behavior while disrupting a focal cortical area via focal electrical stimulation. We used a novel paradigm of individualized direct cortical stimulation to examine the association between creative thinking and the DN. Preoperative resting-state fMRI was used to map the DN in individual patients. A cortical area identified as a DN node (study) or outside the DN (controls) was stimulated while the participants performed an alternate-uses-task (AUT). This task measures divergent thinking through the number and originality of different uses provided for an everyday object. Baseline AUT performance in the operating room was positively correlated with DN integrity. Direct cortical stimulation at the DN node resulted in decreased ability to produce alternate uses, but not in the originality of uses produced. Stimulation in areas that when used as network seed regions produced a network similar to the canonical DN was associated with reduction of creative fluency. Stimulation of areas that did not produce a default-like network (controls) did not alter creative thinking. This is the first study to causally link the DN and creative thinking.

INTRODUCTION

Creativity, traditionally described as the ability to produce novel and useful ideas [1], has played a major role in the establishment of modern culture and civilization. Creative thinking is essential to the daily functioning of modern human beings and allows for inspirational problem solving, technological and artistic advancement. This complex, multi-factorial cognitive process cannot be linked to a specific cerebral anatomical area, such as primary motor or sensory cortices, or to the activity of individual neurons, and instead is assumed to be network-dependent [2]. With the development of robust whole-brain functional imaging, higher cognitive functions are increasingly associated with large-scale cortical networks. These networks are comprised of distributed neuronal ensembles that are spatially dispersed but temporally synchronized [3]. Large-scale neuronal networks are nowadays decipherable using advanced functional imaging and computational methods and are thought to subserve complex abilities, such as attention, executive function, and more [4–6]. The Default Network (DN) is a well-explored, large-scale, association cortical network traditionally linked with internal mentation [7, 8]. Its increased activity is associated with decreased performance in externally driven tasks, and it conversely demonstrates task-induced deactivation when focus is shifted to external stimuli [9]. Recent evidence suggests that connectivity between areas traditionally associated with the DN may underlie the ability to carry out creative thinking [1, 10]. In addition, DN interactions with the salience and executive networks, ensembles that are not traditionally functionally linked, are thought to underlie creative thinking [11].

Heretofore, despite many studies demonstrating correlation between the DN, other large-scale cortical networks, and creativity, no causal relation has been shown. While there have been publications describing transcranial disruption of an anatomical area, and associated impairment in DN related functions such as episodic memory [12] and simulation [13], these have targeted the canonical DN and did not use individualized DN mapping. In addition, several technical limitations associated with transcranial stimulation limit the ability to establish such causality or identify relationships at the individual participant level.

We utilized the unique experimental platform of awake brain surgery for resection of a primary brain tumor to explore the effects of DN node stimulation. During routine surgery near

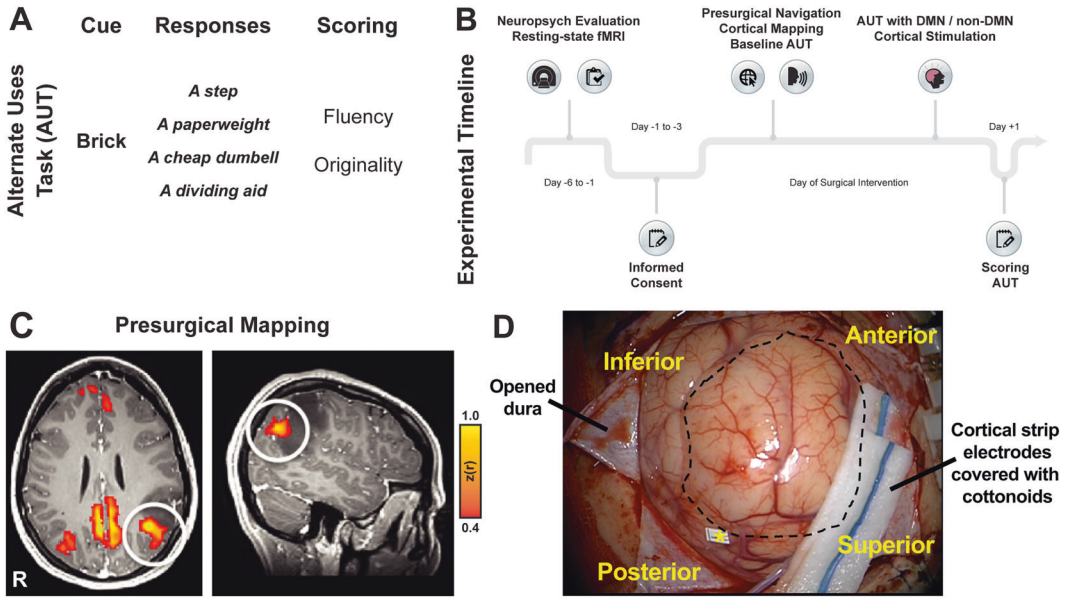

Fig. 1 Study design. A Alternate uses task (AUT). An example of a task cue, followed by potential common alternate uses a participant may produce. Each item was scored for fluency and originality creativity sub-components. **B** The experimental timeline from participant recruitment to postoperative period. **C** Individualized default network (DN) map. Seed-based whole-brain correlation maps were derived from the posterior cingulate cortex (PCC) region of interest. For each study participant, similar DN functional connectivity was derived individually and a target stimulation site was classified either as DN node (white circle) or non-DN site (i.e., outside the correlation map; not shown here). Stimulation sites were chosen such that they would be accessible intraoperatively. **D** An example intraoperative view of exposed tumor (dotted black line represents tumor surface circumference) and the target DN node for direct cortical stimulation as identified by intraoperative navigation (yellow asterisk).

eloquent brain regions, cortical mapping via electrical stimulation (direct cortical stimulation, DCS) is performed to identify functional cortical areas and thus preserve crucial functions, such as speech. Traditionally, intraoperative mapping identifies basic functions of sensation, motor, and speech; higher cognitive functions that are network-dependent are not mapped. DCS allows for the temporary inhibition of a limited cortical area using a bipolar stimulator that minimizes current spread to a ~2 mm sphere [14]. To investigate the possible connection between the DN and creative thinking, we examined the effect of DCS of a preoperatively-identified DN node on the ability to perform creative thinking. Patients who agreed to participate in this study underwent DCS of an individually mapped DN node (study) as extracted from preoperative resting state-based functional connectivity fMRI mapping of this network, or a non-DN stimulation (control). To evaluate creative thinking, we utilized the *alternate uses task* (AUT; Fig. 1A), a well-validated creativity task in which the subject needs to provide varied, alternate possible uses for everyday common objects [15]. The AUT assesses divergent thinking, which is widely considered to be an important antecedent of creativity because it involves the ability to consciously generate new ideas that branch out and allow for many possible solutions to a given problem, and is scored based on the originality and the number of valid uses [15]. The effects of stimulation on two main components of creative thinking, originality and creative fluency, as expressed by the relative domains in the AUT, were examined. We hypothesized that disruption of DN synchronization by artificial non-physiologic electrical stimulation would affect the ability to perform creative thinking (Fig. 1B).

METHODS

Patient selection and experimental procedure

All patients participating in this experiment willfully signed an informed consent form, and this experiment was approved by the Tel Aviv Medical Center ethics committee (0378-16-TLV). Included were patients with gliomas that were located in or near eloquent brain areas in the dominant hemisphere and were scheduled for clinically-indicated awake craniotomy for resection of their tumor. All patients had intact language functions preoperatively, and Hebrew was their native tongue. All patients underwent a thorough pre-operative neuropsychological evaluation, fMRI for determination of language dominance, and mapping of their DN (see below for details). Neurocognitive profiles were assessed preoperatively using the NeuroTrax computerized cognitive testing battery (NeuroTrax Corp., Bellaire, TX) [16]. Each patient's DN map was uploaded to the intraoperative neuro-navigation system (BrainLab AG, Feldkirchen, Germany) and used clinically to locate the tumor and plan the craniotomy and subsequent resection of the tumor. After rigid positioning in a head holder in the operating room, each patient underwent a baseline evaluation of language functions. Next, a tumor-tailored craniotomy was done under regional nerve blocks and local anesthetics as is customary in our center [17, 18]. Mapping for language functions was carried out following craniotomy and dural opening, covering the entire exposed cortical surface. Intraoperative mapping was carried out in two stages. First, in order to control for interference with language functions, naming, verb generation, and comprehension were tested. Language function baselines were established inside the operating room following cortical exposure, but before cortical stimulation, to control for anxiety and drug related effects on performance and difference in experimental setting. If any language effects were noted during mapping, or if clinical/sub-clinical electrical seizures were identified (by intraoperative electrocortiography) during DCS the participant was excluded from this study. Then, a baseline AUT consisting of five items was performed with no stimulation. Next, we located the DN node as mapped preoperatively using the intraoperative navigation system and, when possible, stimulated the node while the participant performed the AUT. The final intraoperative location of the DCS was documented on the neuro-navigation system. For control participants who did not have a DN node close to the craniotomy, we stimulated a cortical area that was verified to be outside the DN as mapped preoperatively, and the stimulation site was documented. Each participant's performance on the AUT was subsequently scored by a neuropsychologist (blind to the stimulation location) and results were compared to baseline and between study and control groups.

DN mapping

Brain imaging was performed at the Wohl Institute for Advanced Imaging, Tel Aviv Medical Center, using a Siemens MAGNETOM Prisma 3.0 T scanner

with a twenty-channel head coil. Anatomical 3D T1-weighted imaging was obtained using SPGR/FLASH sequences with 1 mm isotropic voxels. All functional whole-brain scans were performed with gradient echo-planar imaging (EPI) sequence of functional T2*-weighted images.

Scan parameters, preprocessing and functional connectivity analysis

For each participant, a six-minute resting-state fMRI scan was acquired (TR = 3000 ms, TE = 35 ms, flip angle = 90°, 44 slices at 3 mm thickness with no gap, 117 repetitions). Preprocessing was done in agreement with widely available pipelines, and as previously described [19, 20]. A functional connectivity measure of the DN integrity was computed as the correlation between time courses in two DN ROIs, posterior cingulate cortex (PCC) and medial prefrontal cortex (mPFC). Specifically, spherical ROIs with 6 mm radius were defined with centers at: $x = 0$, $y = -60$, $z = 30$ for PCC and −1, 49, 5 for mPFC (coordinates defined in the Montreal Neurological Imaging [MNI] atlas space). Individual DN integrity was calculated as the whole brain connectivity of the PCC ROI (thresholded at z (r) of 0.4). Similarity between individual DN maps derived from a stimulation ROI and the canonical DN was estimated using the Sørensen-Dice similarity coefficient between the stimulation seed-based map (thresholded at $z(r)$ of 0.2) and the DN from Yeo et al. [3].

Alternate uses task (AUT)

Different items for the AUT were used at baseline and during stimulation to avoid learning effects and were identical across all participants (baseline—shoe, button, bedsheet, nail, paper clip; stimulation—box, car tire, cup, pencil, can). Participants were blinded to the study rationale and task and were informed that the study goals were to improve the ability to avoid resection-induced deficits on language and related high-order cognitive functions. Patients were only instructed to provide alternate uses for the sample item (newspaper, and its possible alternate uses – start a fire, wrap garbage, swat flies, fill boxes, line drawers, make up kidnap note, for example) before the baseline task was performed and again before the stimulation task. Following Shamay-Tsoory and colleagues [21, 22], participants were asked to think of original uses of everyday objects. Participants were given up to one minute to complete each item of the task for a total of 5 minutes for each part of the experiment. The intraoperative testing was recorded and documented (following participants' consent) and blindly graded postoperatively. Measures of originality, based on a previously validated infrequency measure, and fluency, average number of valid creative uses given for each task item, were derived. For the fluency score, the number of alternative uses that did not recapitulate the original use (i.e., pencil—to write, to draw etc.) were counted. For the originality score, we utilized a previously constructed and validated answer database of 92 normal healthy adults. This allowed for a valid response frequency estimation. Each use was scored based on the infrequency in this answer database (score of 0 if >5% of participants provided it, 1 is 2–5%, 2 if <2%). For example—alternate uses for a shoe (common use to wear on feet) included "door stopper" 14.1%, score of 0 in originality, "make loud noises—bang with" 2.1% score of 1, and "put on the head for balance training" 1.08% score of 2. According to this, average originality and creative fluency scores were calculated for each patient and for each experimental condition. This scoring method is well validated and was chosen as it is objective, thus minimizing observer bias [23, 24]. In addition, this advantage is especially important as this study focused on the change in AUT score following DN stimulation, and did not attempt to predict future overall creative ability based on the baseline score. Both the participant and the examiner were blinded to the direct cortical stimulation location.

Intraoperative direct cortical stimulation

Direct cortical stimulation was performed using the Ojemann cortical stimulator (Radionics Inc., Burlington, MA, USA). For language mapping, current intensity was modified by increasing the amplitude in 2 mA increments, from a baseline of 2 mA up to 8 mA. If seizures were observed, ice water was irrigated over the brain, and the study was aborted. During cortical mapping for language functions, observed behavioral effects and performance dysfunctions (e.g., speech arrest, anomia, etc.) were tagged and documented with regard to both anatomical and radiological location, as well as to the applied current intensity. If no effect was produced following language mapping, the stimulator was set to 4 mA, and stimulation was performed for 10 sec followed by 10 sec without stimulation until the completion of the task item.

RESULTS

A total of 13 out of 22 eligible patients who underwent awake resection of a primary brain tumor were included in this study (Table 1). Nine patients were excluded from this study, six due to intraoperative clinical or electrocorticographic seizures and 3 due to speech impairments induced during language mapping of the exposed cortex.

All patients were high-functioning and cognitively intact (see table S1 for detailed cognitive assessment available for 12/13 patients) with no language disturbances at baseline following a preoperative neuropsychological evaluation. In addition, all patients were neurologically intact as documented in their hospital admission neurological examination. All patients had undergone assessment of a baseline creativity score of >0 in both AUT domains (originality and fluency of creative thinking), and

thus were eligible to participate in this experiment. All patients willfully agreed to participate and signed an informed consent prior to surgery. Nine participants underwent stimulation of a DN node as derived from resting-state functional connectivity MRI posterior cingulate cortex (PCC) region of interest (ROI) seed-based whole-brain correlation map. Cases where the node was in proximity to the tumor, and inside the cortical region that was meant to be exposed according to a clinically-planned craniotomy participated in the experiment as subjects, and underwent stimulation of the node. Four participants who did not have an accessible DN node underwent stimulation of a non-DN cortical area and served as the control group. Importantly, prior to participation in this experiment, the exposed cortex was mapped intraoperatively for language functions as is the case with all awake craniotomies performed at our center. If any language disturbances were produced, or if a seizure (clinical or subclinical, as recorded by electrocorticography) was induced by the stimulation, the participant was excluded from this study (Fig. 1).

To validate AUT in the operating room setting, we correlated the baseline scores obtained during surgery (prior to stimulation) with each individual participant's correlation strength (z(r)) between PCC and the left medial prefrontal cortex (mPFC), a surrogate marker of DN integrity (*14*, Fig. 2A). Fluency was positively correlated with PCC-mPFC correlation ($r_{(11)} = 0.68$, $P = 0.007$, Fig. 2B), while originality was not ($r_{(11)} = -0.44$, $P = 0.11$, Fig. 2C).

We first examined the effects of stimulation, and stimulation site (DN node compared to loci outside of the DN) on creative thinking. A two-way ANOVA was conducted to examine the effects of DCS and Stimulation Site on the AUT Fluency Score. This analysis revealed an effect of DCS on Fluency, which was reduced following stimulation ($F(1,11) = 7.47$, $P = 0.019$), but none with Stimulation Site ($F(1,11) = 0$, $P = 0.99$). Surprisingly, no interaction was found between DCS and Stimulation Site ($F(1,11) = 0$, $P = 0.72$), suggesting a mismatch between preoperative planning and operative localization of the DN. A two-way ANOVA comparing the effects of DCS and Stimulation Site on Originality Score revealed no effects (Stimulation: $F(1,11) = 0$, $P = 0.99$; Stimulation Site: $F(1,11) = 0.79$, $P = 0.39$; Stimulation × Stimulation Site: $F(1,11) = 1.79$, $P = 0.21$). These findings indicate that in our cohort, DCS of the left hemisphere specifically affected creative fluency but not originality, and this effect is independent of planned stimulation site.

Next, in order to further validate these findings and to minimize the potential effects of anatomical or surgically-associated disruptions on stimulation accuracy, such as intraoperative brain shift, we conducted a post-hoc analysis in which a seed was placed at the final point of stimulation (as was recorded intraoperatively using the navigation system). These ROIs (Fig. 3A) were used to calculate individualized whole-brain correlation maps, which were then compared to the canonical DN as defined by Yeo et al. [3]. First, we validated that the group DN map as derived from a PCC seed region overlaps with the canonical DN map (Fig. 3B). Next, we hypothesized that in participants where the final stimulation location derived seed-based maps are more similar to canonical DN, DCS will yield a more prominent effect on creative thinking (see Fig. 3C for individual participant's examples of a stimulation ROI derived maps that show high (i) vs. low (ii) similarity to the canonical DN). Next, for each participant, we computed the overlap between the individualized stimulation-based map and the canonical DN map using the Sørensen-Dice similarity coefficient score (Fig. 3D). Then, we divided the cohort into two subgroups based on the Similarity score, and examined the effects of DCS in these two subgroups (Fig. 3E). A two-way ANOVA was conducted to examine the effect of Stimulation, and Similarity on the AUT Fluency Score. The analysis revealed that while Similarity did not have a direct effect on Fluency ($F_{(1,11)} = 0.02$, $P = 0.91$), it demonstrated a robust interaction with Stimulation ($F_{(1,11)} = 12.62$, $P = 0.005$), with a stronger effect of stimulation in individuals in the high Similarity subgroup. Importantly, examining this effect in individuals based on the anatomical location of the stimulation site (Fig. 3F), we found that the change in Fluency could be produced by stimulation of parietal, frontal and temporal regions, suggesting that it is network-dependent. In addition, no effect or interaction were found for Originality (Similarity: $F_{(1,11)} = 0.1$, $P = 0.76$; Stimulation × Similarity: $F_{(1,11)} = 0.56$, $P = 0.47$). Collectively, these findings suggest that stimulation in areas that are more connected to the DN (as defined by the canonical DN) produces a strong effect on fluency, but not originality.

DISCUSSION

Using a novel experimental approach—disruption of individually identified regions within the default network using direct cortical stimulation in awake patients performing a divergent thinking task—we demonstrate a causal link between the default network and creative fluency. Stimulation of left (dominant) hemisphere DN nodes had no effect on originality scores, and stimulation outside the DN did not cause any disruption to creative thinking. We further validated this finding by demonstrating that direct cortical stimulation-induced impairment of creative fluency was specific to and more prominent in participants who were stimulated in DN-associated regions.

Creative cognition, a hallmark of higher cognitive function, is essential for human evolution and progress. The ability to perform creative thinking in both abstract forms, such as art, and in complex problem solving, such as science, necessitates multi-modal information integration together with introspective thought processes. This manifests in the ability to link seemingly unrelated elements [25, 26]. These qualities may be explained by the unexpected synchronization of spatially segregated nodes of different computational modalities. Recent creative cognition models have postulated that creativity emerges through a synchronization between three cortical networks—the DN, salience and the executive control network [11, 27]. Each of these networks is considered to accommodate a different aspect of creative thinking. The DN, a network that mediates spontaneous cognition, or the "stream of consciousness", is thought to contribute to the flexible retrieval of memories and generation of ideas [7]. The salience network is thought to filter useful and novel candidate ideas and forward them to the executive control network that constrains this stream towards a specific goal [28]. Various studies have correlated DN integrity or strength of internal correlation between different hubs with creativity psychometrics. Takeuchi et al. showed that reduced task-induced deactivation of the PCC is associated with increased creativity, postulating that reallocation of cognitive resources to DN domains instead of working memory may be responsible for enhanced creative thinking [29]. Abraham et al. used a conceptual expansion fMRI task, a specific form of divergent thinking, and found that both salience and DN nodes are overactivated in participants with higher creativity, suggesting that individual differences are dependent on network integration [30]. Benedek et al. [31], using a block design fMRI AUT, examined the functional organization of divergent thinking. In their study of creative idea generation, a deactivation of ventral attention components, and of the PCC within the DN, was observed, while increased activity was noted in other DN nodes, such as the prefrontal cortex, and the hippocampal formation. These results suggest that different aspects of creativity are modulated by specialized DN subcomponents. In another work, examining chains of free associations, Marron et al. demonstrated substantial involvement of the DN in free association production compared to other forms of language production [32]. Interestingly, in their study the majority of reported activations were in the left hemisphere, providing a

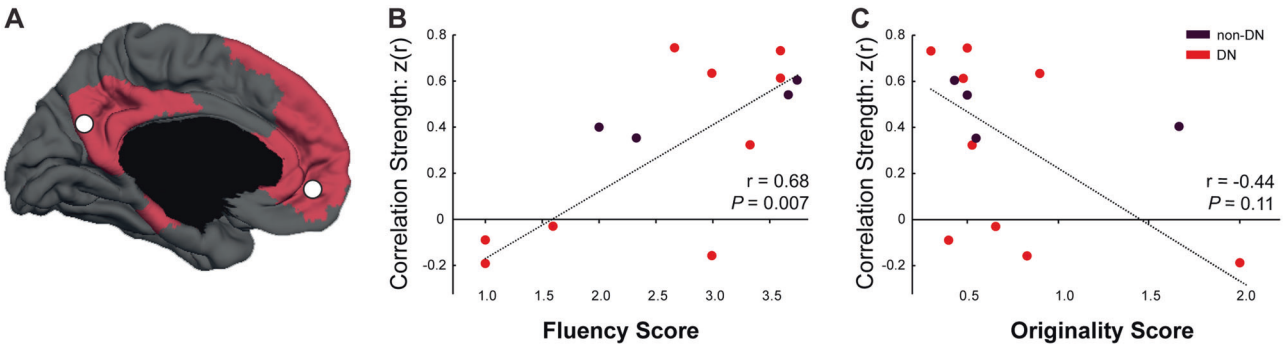

Fig. 2 Intraoperative performance in the Alternate Uses Task (AUT) relative to Default Network (DN) resting-state functional connectivity MRI strength. A For each participant, the correlations between two key nodes of the DN, PCC and mPFC were computed. The extent of DN coverage, derived from Yeo et al. [3], is depicted on the medial surface (red) along with the PCC and mPFC seed region-of-interest locations (denoted by white filled circles). **B** AUT fluency score at baseline (no stimulation condition) is correlated with PCC–mPFC Fisher's z-transformed Pearson's *r* correlation strength (*z*(*r*)). **C** AUT originality score is not correlated with PCC–mPFC correlation strength.

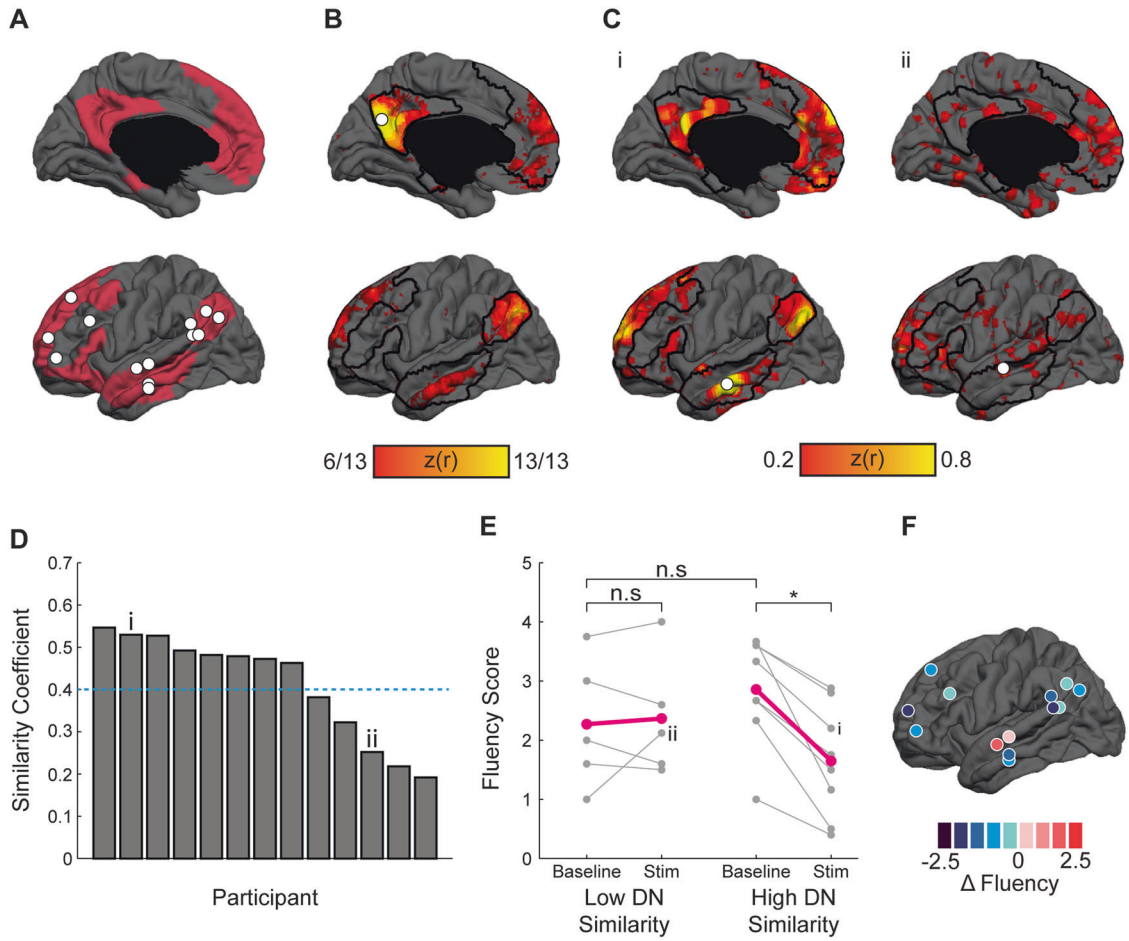

Fig. 3 Direct cortical stimulation of the DN impairs creative fluency. A DN spatial extent adopted from Yeo et al. [3] is depicted. Direct cortical stimulation sites in the DN ($n = 9$) and in control regions ($n = 4$) are depicted (filled white circles). **B** The entire cohort ($n = 13$) DN map was extracted using a PCC seed region (denoted by a filled white circle). The map shows the convergence of individual PCC maps thresholded at *z*(*r*) of 0.2. **C** Representative individual participants' maps derived from a seed region of interest within the DN placed at the stimulation site (filled white circle). A representative participant that demonstrates a map resembling the canonical DN (**i**), and a participant that does not (**ii**). **D** Individual participants overlap with the canonical DN (similarity coefficient) between the map obtained from the stimulation site ROI and the canonical DN. Participants i and ii are marked. **E** Participants with a similarity coefficient of 0.4 and above demonstrated significant impairment in creative fluency following direct cortical stimulation (*$P < 0.05$, n.s. non-significant; participants i and ii are marked, purple lines represent group average). **F** The relationship between direct cortical stimulation anatomical location and stimulation-induced changes in fluency are denoted as the difference in score change from baseline to the stimulation condition (filled dark-blue to dark-red circles).

possible explanation for our finding of decreased creative fluency following DN DCS. The emerging concept of sub-networks within the DN (for review see Buckner and DiNicola [33]) that are associated with various aspects of creativity is further supported by Shamay-Tsoory et al. [21]. This study, on which we relied methodologically, examined patients with localized lesions utilizing the same version of the AUT used here. Their finding of a correlation between right hemispheric lesions in the mPFC and decreased originality led them to associate this region with less linear cognitive processes. Interestingly, this finding is in line with our results demonstrating reduced creative fluency with DCS of left hemisphere DN and no change in originality, further suggesting a role for right hemisphere DN in original thinking. It should be noted that verbal and creative fluency are well correlated, and may partially overlap in function [34, 35]. However, in all participating subjects, the cortex exposed during surgery was thoroughly mapped for language functions (stimulated systematically while evaluating for naming, comprehension, and free speech). In all of the included subjects there was no disruption of speech-related functions, suggesting that the observed effect is creative fluency-specific, and not related to language disruption in general, further emphasizing the role of the DN in creative cognition. In addition, none of the patients were stimulated in the left inferior frontal gyrus, a main node in verbal fluency, which may disrupt both of these overlapping functions. In addition, recent evidence supports the existence of at least two DN subnetworks that are functionally specialized, and anatomically distinct in individual patients [36]. Two main subcomponents of the DN were recently characterized as mediating either theory of mind, or episodic projection [37]. This intra-DN parcellation may, in part, explain the variability in our participants' performance, as well as the fact that only some components of creativity were decreased by DCS of an individual's DN. An alternative explanation for the selective disruption of creative fluency seen following DN DCS is that the main contribution of the DN to divergent thinking is through mediation and retrieval of memories (for review see Hass and Beaty, 2018 [38]). This possible interference with episodic retrieval, is in line with recent evidence that boosting of episodic memory led to better performance in AUT [39]. As it is extremely rare for patients harboring gliomas in the non-dominant hemisphere to undergo awake resection, a complementary experiment adjudicating these two possible explanations (i.e., demonstrating reduced originality following right-sided DN DCS) was not performed in our particular setting, but is a subject for future research.

Several attempts were made over recent years to map, using electrical stimulation, what is termed "non-eloquent" cortex [40]. One such attempt by Foster et al. targeted the postero-medial cortex, a key node of the DN, via depth electrodes implanted in epilepsy patients [41]. In their study, and in concordance with our experience, when mapping areas of associative networks, no effect was evident. This lack of cognitive effects may be explained by the lack of an appropriate task or by the lack of patient-specific, network-based targets for stimulation. In our study design, the stimulated areas that yielded significant behavioral effects upon stimulation were those that produced a DN-like map at the individual level. Also, patients who demonstrated cognitive impairments or lack of creative ability in the preoperative neuropsychological assessment were excluded, as they were not expected to be able to fully participate in such a task.

We are aware of the limitations in our study design, as the number of subjects is limited and stimulation areas were limited to the left hemisphere. In addition, the number of task items and the time allowed for each item may influence the performance in AUT [42]. However the time frame in this special setting is extremely constrained [43], and we believe that this effect was minimized by the study design in which each participant served as their own control with no comparison of creative ability to an external cohort.

These limitations are a derivative of the unique experimental setting in which the human cortex is stimulated while an awake patient performs a task in the operating room. Recently, Natu et al. demonstrated that stimulation of the PCC in epilepsy patients implanted with depth electrodes impairs episodic memory recall, while no other subjective experience was elicited. In addition, following extended periods of stimulation of the PCC, a modulation of the PCC-hippocampal network, a key component of the DN, was evident [44]. These works, taken together with the findings presented here, set the stage for future interventional studies targeting associative networks-related functions that may greatly advance our understanding of the complex processes that lie at the core of human essence. These findings suggest a future approach for the mapping and preservation of creativity and higher cognitive functions in patients undergoing brain surgery.

Abstract

The circadian system of mammals is composed of a hierarchy of oscillators that function at the cellular, tissue, and systems levels. A common molecular mechanism underlies the cell-autonomous circadian oscillator throughout the body, yet this clock system is adapted to different functional contexts. In the central suprachiasmatic nucleus (SCN) of the hypothalamus, a coupled population of neuronal circadian oscillators acts as a master pacemaker for the organism to drive rhythms in activity and rest, feeding, body temperature, and hormones. Coupling within the SCN network confers robustness to the SCN pacemaker, which in turn provides stability to the overall temporal architecture of the organism. Throughout the majority of the cells in the body, cell-autonomous circadian clocks are intimately enmeshed within metabolic pathways. Thus, an emerging view for the adaptive significance of circadian clocks is their fundamental role in orchestrating metabolism.

INTRODUCTION

Circadian rhythm: an endogenously generated oscillation with a period of ~24 h; can entrain to external cues and is temperature compensated

Suprachiasmatic nucleus (SCN): the site of the master circadian pacemaker in mammals, comprising ~20,000 individual neurons that couple to form a robust oscillatory network

Living systems possess an exquisitely accurate internal biological clock that times daily events ranging from sleep and wakefulness in humans to photosynthesis in plants (Takahashi et al. 2008). These circadian rhythms represent an evolutionarily conserved adaptation to the environment that can be traced back to the earliest life forms. In animals, circadian behavior can be analyzed as an integrated system—beginning with genes and leading ultimately to behavioral outputs. In the past 15 years, the molecular mechanism of circadian clocks has been uncovered by the use of phenotype-driven (forward) genetic analysis in a number of model systems (Lowrey & Takahashi 2011). Circadian oscillations are generated by a set of genes forming a transcriptional autoregulatory feedback loop. In mammals, these include *Clock*, *Bmal1*, *Per1*, *Per2*, *Cry1*, and *Cry2*. Researchers have identified another dozen candidate genes that play additional roles in the circadian gene network such as the feedback loop involving *Rev-erbα*.

Early work on mammalian rhythms used rhythmic behavior as a readout of the clock, and the hypothalamic suprachiasmatic nucleus (SCN) was identified as the dominant circadian pacemaker driving behavioral rhythms (Welsh et al. 2010). However, the discovery of "clock genes" led to the realization that the capacity for circadian gene expression is widespread throughout the body (Dibner et al. 2010). Using circadian gene reporter methods, one can demonstrate that most peripheral organs and tissues can express circadian oscillations in isolation yet still receive, and may require, input from the SCN in vivo. The cell-autonomous clock is ubiquitous, and almost every cell in the body contains a circadian clock (Balsalobre et al. 1998, Nagoshi et al. 2004, Welsh et al. 2004, Yoo et al. 2004). It is now evident that the circadian oscillators within individual cells respond differently to entraining signals, control different physiological outputs, and interact with each other and with the system as a whole. These discoveries have raised a number of questions concerning the synchronization and coherence of rhythms at the cellular level as well as the architecture of circadian clocks at the systems level (Hogenesch & Ueda 2011). Here we discuss recent work that addresses these organizational issues and examines a number of levels of complexity within the circadian system. We review mechanisms by which circadian clocks govern biological processes as well as mechanisms by which these processes feed back into the circadian system. Perhaps the most important example of this is the intimate and reciprocal interaction between the circadian clock system and fundamental metabolic pathways (Bass & Takahashi 2010, Green et al. 2008, Rutter et al. 2002). In addition, there exist additional oscillatory processes in the circadian time domain that are observable in the presence of scheduled meals or methamphetamine

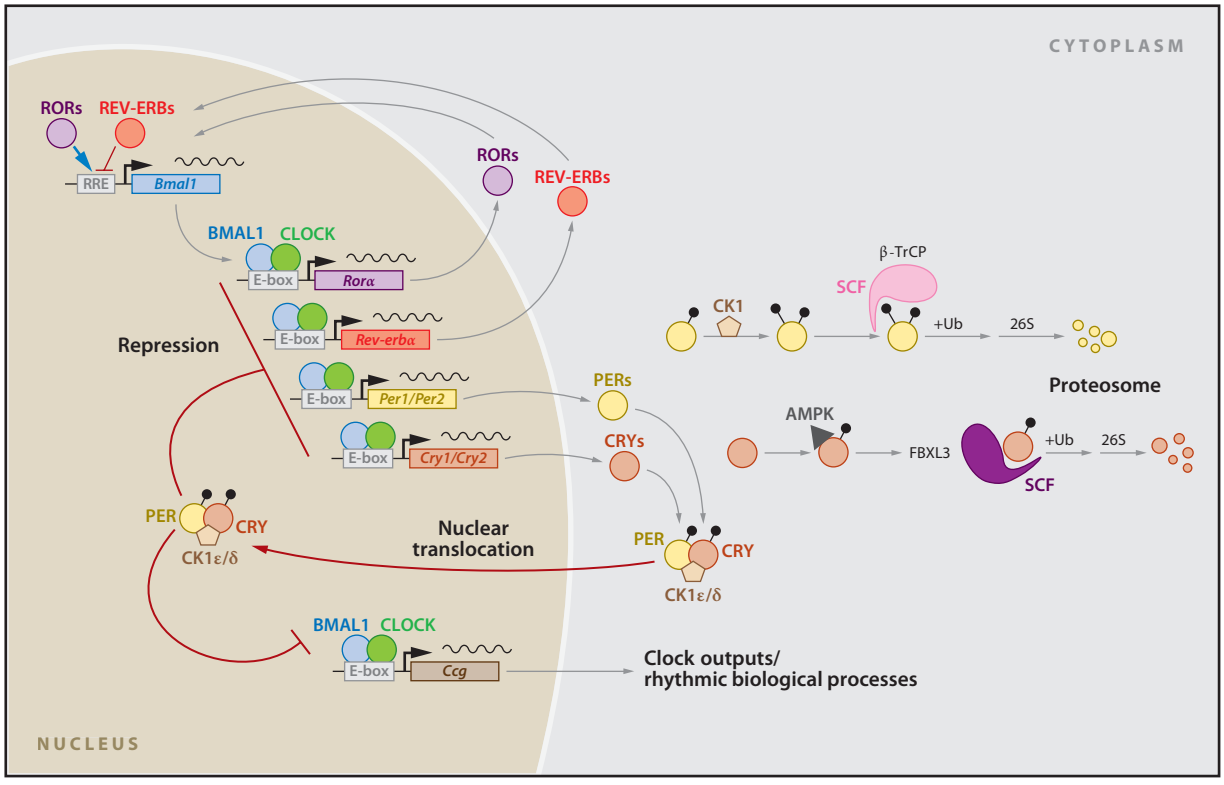

Figure 1

The molecular mechanism of the circadian clock in mammals. Constituting the core circadian clock is an autoregulatory transcriptional feedback loop involving the activators CLOCK and BMAL1 and their target genes *Per1*, *Per2*, *Cry1*, and *Cry2*, whose gene products form a negative-feedback repressor complex. In addition to this core transcriptional feedback loop, other feedback loops are also driven by CLOCK:BMAL1. One feedback loop involving *Rev-erbα* and *Rorα* that represses *Bmal1* transcription leads to an antiphase oscillation in *Bmal1* gene expression. CLOCK:BMAL1 also regulates many downstream target genes known as clock-controlled genes (Ccg). At a post-transcriptional level, the stability of the PER and CRY proteins is regulated by SCF (Skp1-Cullin-F-box protein) E3 ubiquitin ligase complexes involving β-TrCP and FBXL3, respectively. The kinases, casein kinase 1ε/δ (CK1ε/δ) and AMP kinase (AMPK), phosphorylate the PER and CRY proteins, respectively, to promote polyubiquitination by their respective E3 ubiquitin ligase complexes, which in turn tag the PER and CRY proteins for degradation by the 26S proteasome complex.

treatment. These oscillators can generate behavioral rhythms in vivo in the absence of the SCN (Honma & Honma 2009).

MOLECULAR MECHANISM OF THE CIRCADIAN CLOCK IN MAMMALS

In mammals, the mechanism of the circadian clock is cell autonomous and arises from an autoregulatory negative-feedback transcriptional network (Lowrey & Takahashi 2004, Takahashi et al. 2008) (**Figure 1**). At the core of this clock network are the transcriptional activators, CLOCK (and its paralog, NPAS2) and BMAL1, which positively regulate the expression of the *Period* (*Per1*, *Per2*) and *Cryptochrome* (*Cry1*, *Cry2*) genes at the beginning of the cycle. *Per* and *Cry* gene products accumulate, dimerize, and form a complex that translocates into the nucleus to interact with CLOCK and BMAL1, repressing their own transcription. This feedback cycle takes ~24 h, and the turnover of the PER and CRY proteins is tightly regulated by E3 ubiquitin ligase complexes. There are additional feedback loops interlocked

with the core CLOCK-BMAL1/PER-CRY loop. Prominent among these is a loop involving *Rev-erbα* (*Nr1d1*) and *Rora*, which are also direct targets of CLOCK-BMAL1. The feedback effects of this loop impinge on the transcription of *Bmal1* (and to a lesser extent on *Clock*) to cause an antiphase oscillation of BMAL1. Other feedback loops involve the PAR-bZip family members, DBP, HLF, and TEF; the bZip protein, E4BP4 (*Nfil3*); and the bHLH proteins, DEC1 and DEC2 (*Bhlhb2*, *Bhlhb3*), all of which are transcriptional targets of CLOCK-BMAL1 (Gachon 2007, Lowrey & Takahashi 2004, Takahashi et al. 2008).

The discovery of a ubiquitous, cell-autonomous clock in mammals has led to a re-evaluation of central and peripheral oscillators: Are they fundamentally similar in mechanism, how do they function in different cellular contexts, and what role does coupling in the central SCN clock play in its functional properties?

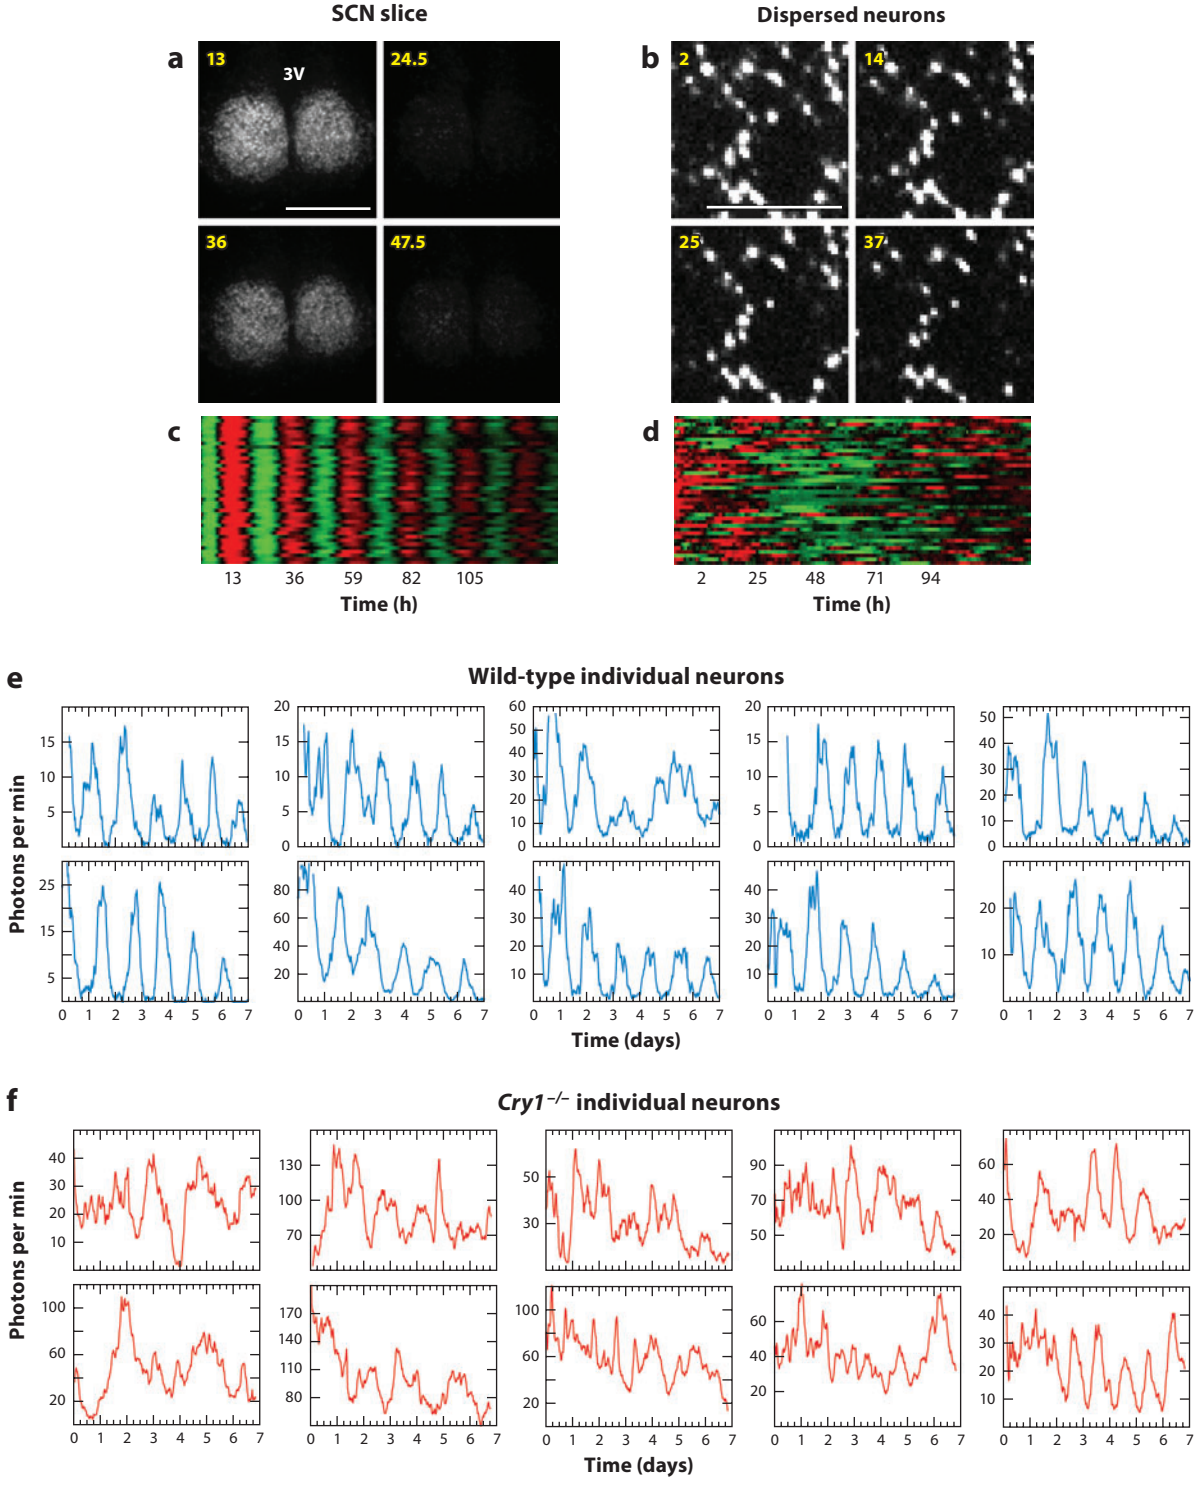
CENTRAL CIRCADIAN OSCILLATORS

The hypothalamic SCN acts as a master pacemaker for the generation of circadian behavioral rhythms in mammals (for a review, see Welsh et al. 2010). Classic work not reviewed here has shown that the SCN is both necessary and sufficient for the generation of circadian activity rhythms in rodents. The SCN receives direct photic input from the retina from a recently discovered photoreceptor cell type termed the intrinsically photoreceptive retinal ganglion cell (ipRGC) (reviewed in Do & Yau 2010). These ipRGCs express a novel photopigment, melanopsin, that renders them intrinsically photosensitive to short-wavelength irradiation. Interestingly, ipRGCs are depolarizing photoreceptors that employ a phototransduction mechanism that is analogous to that seen in invertebrate photoreceptors. The photoresponse in ipRGCs has slow kinetics and a relatively high threshold to light, making them ideally suited to function as circadian photoreceptors, which must integrate light information over relatively long durations and must be insensitive to transient light signals that are not associated with the solar light cycle. Although ipRGCs appear to be optimal circadian photoreceptors, they do not act alone; rod and cone photoreceptors also have photic inputs to the SCN. Interestingly, these nonvisual inputs from rods and cones to the SCN are mediated by the ipRGCs (Chen et al. 2011, Guler et al. 2008). An emerging theme is that melanopsin-positive ipRGCs are involved in a surprisingly broad array of nonvisual photic responses in mammals. The complexity of the ipRGCs and their contribution to circadian rhythms and other behaviors are beyond the scope of this discussion, but recent reviews have covered this topic in depth (Do & Yau 2010, Schmidt et al. 2011).

Suprachiasmatic Nucleus

The SCN is composed of ~20,000 neurons, each of which is thought to contain a cell-autonomous circadian oscillator. The SCN functions as a network in which the population of SCN cells are coupled together and oscillate in a coherent manner (Herzog 2007). The dynamics of the spatial and temporal coordination of rhythms in the SCN have been studied recently, enabled by the advent of single-cell circadian reporter technology, which has revealed unexpected complexity in the temporal architecture of the nucleus (Evans et al. 2011, Foley et al. 2011, Yamaguchi et al. 2003). At the single-cell level, SCN neurons exhibit a wide range in cell-autonomous circadian periods that vary from 22 h to 30 h (Ko et al. 2010, Liu et al. 1997, Welsh et al. 1995). Intercellular coupling among SCN neurons acts to mutually couple the entire population to a much narrower range that corresponds to the circadian period of the locomotor activity rhythm, which is extremely precise (a standard deviation in period that is ~0.2 h or 12 min in mice) (Herzog et al. 2004). The heterogeneity in intrinsic period of the SCN cells confers at least two important functions: phase lability and phase plasticity. The phases of the rhythms of individual SCN neurons are highly stereotyped

Annu. Rev. Neurosci. 2012.35:445-462. Downloaded from www.annualreviews.org
by Stanford University - Main Campus - Green Library on 07/10/12. For personal use only.



anatomically and appear as a wave that spreads across the nucleus over time (Evans et al. 2011, Foley et al. 2011, Yamaguchi et al. 2003). Intrinsically shorter-period cells have earlier phases and intrinsically longer-period cells have later phases within the SCN, reflecting phase lability (Yamaguchi et al. 2003). Under different photoperiods (e.g., long- versus short-photoperiod light cycles), the waveform of the SCN population rhythm is modulated such that in short photoperiods the SCN waveform is narrow and has a high amplitude, whereas in long photoperiods the SCN waveform is broad and has a low amplitude, reflecting phase plasticity (Inagaki et al. 2007, VanderLeest et al. 2007). In addition to the heterogeneity of SCN oscillator period and phase, it has been proposed that the cell-autonomous SCN oscillators are not intrinsically uniformly robust (Webb et al. 2009). Rather, the intercellular coupling of SCN neurons appears critical to the robustness of the SCN network oscillatory system.

With the discovery of peripheral oscillators (Balsalobre et al. 1998, Yamazaki et al. 2000, Yoo et al. 2004) and the apparent ubiquity of clock mechanisms (Yagita et al. 2001), a critical question arises concerning the similarity and differences in the SCN pacemaker as compared with peripheral oscillators. To address this question, Liu et al. (2007a) examined whether canonical clock mutations previously assessed in vivo affected the SCN and peripheral oscillators in a similar manner. Using *Per2::luciferase* reporter mice, they found that the effects of the *Period* and *Cryptochrome* loss-of-function mutations were the same in SCN explants as those seen previously at the behavioral level. By contrast, in peripheral tissues, single loss-of-function mutations that are subtle at the behavioral level, such as *Per1* or *Cry1* knockouts, produced very strong loss-of-rhythm phenotypes. Interestingly, the effects of these mutations are cell autonomous in both fibroblasts and in isolated SCN neurons, supporting the idea that the cell-autonomous clock is similar in these two cell types. However, when the SCN population is coupled, the effects of these mutations are non-cell autonomous. This occurs as a consequence of the intercellular coupling in the SCN network, which is capable of rescuing a cell-autonomous defect in the individual cells (**Figure 2**). This transformation of the oscillatory capability of SCN neurons from damped to self-sustained is an important illustration of the robustness of the SCN network. Indeed, Ko et al. (2010) have found that the SCN network is capable of generating oscillations in the circadian domain in the complete absence of cell-autonomous oscillatory potential. In *Bmal1*-knockout mice, which are arrhythmic at the behavioral level, SCN explants unexpectedly express stochastic oscillations in the circadian range that are highly variable. When the individual cells are no longer rhythmic, the coupling pathways within the SCN network can propagate stochastic rhythms that are a reflection of both feed-forward coupling mechanisms and intracellular noise. Thus, in a manner analogous to central pattern generators in neural circuits, rhythmicity can arise as an emergent property of the network in the absence of the component pacemaker or oscillator cells.

In addition to the generation of sustained oscillations by the SCN network, the SCN is also robust to perturbations from environmental inputs. In wild-type mice, the phase-resetting curve to light pulses is characteristic of Type 1 or weak resetting (low amplitude) (Vitaterna et al. 2006). This is a reflection of the robustness of the SCN pacemaker because inputs such as light can perturb the phase of the oscillation only to a limited extent. In contrast, genetic mutations that lower the amplitude of the molecular oscillation in the SCN lead to increases in the sensitivity to light-induced phase shifts (Type 0 resetting) without changing the strength of the light signals impinging on the SCN (Vitaterna et al. 2006). Similar effects are seen with temperature cycles. Peripheral oscillators are exquisitely sensitive to the phase-shifting effects of temperature and can be entrained strongly by low-amplitude temperature cycles that are equivalent to the circadian fluctuation in core body temperature

(~2.5°C oscillation in mice) (Brown et al. 2002, Buhr et al. 2010). Interestingly, the SCN is resistant to entrainment by low-amplitude temperature cycles, and this resistance depends on the intercellular coupling of SCN neurons (Abraham et al. 2010, Buhr et al. 2010). As was the case for genetic mutations on the generation of rhythms, the effects of temperature perturbations on the SCN are cell autonomous when intercellular coupling is eliminated. Thus, both SCN and peripheral oscillators are sensitive to temperature cycles at the cell-autonomous level; however, coupling within the SCN network confers robustness and makes the SCN network resistant to temperature perturbations. As discussed below, the temperature resistance of the SCN makes functional sense because the SCN drives the body-temperature rhythm, and this temperature signal, which can serve as an entraining signal for peripheral clocks, may otherwise feed back and interfere with the SCN (Buhr et al. 2010).

PERIPHERAL CLOCKS

Rhythms of clock gene and/or protein expression have been observed in cells and tissues throughout the body in mammals, and these rhythms persist in culture, demonstrating that non-SCN cells also contain endogenous circadian oscillators (Balsalobre et al. 1998, Yamazaki et al. 2000, Yoo et al. 2004). Although the core clock machinery is conserved in these different cellular clocks, there are significant differences in the relative contributions of the individual clock components, as well as in the manner in which these peripheral clocks are reset and in the output pathways that are under their control. These endogenous cellular clocks drive extensive rhythms of gene transcription, with 3–10% of all mRNAs in a given tissue showing circadian rhythms in steady-state levels (Akhtar et al. 2002, Duffield et al. 2002, Hughes et al. 2009, Miller et al. 2007, Panda et al. 2002, Storch et al. 2002). However, the genes that are under circadian control are largely nonoverlapping in each tissue, reflecting the need for temporal control of the cellular physiology relevant to each unique cell type. As a result, the circadian clock exerts broad-ranging control over many biological processes, including many aspects of metabolism such as xenobiotic detoxification (Gachon et al. 2006), glucose homeostasis (Lamia et al. 2008, Marcheva et al. 2010, So et al. 2009, Turek et al. 2005), and lipogenesis (Gachon et al. 2011, Le Martelot et al. 2009).

Entrainment: synchronization and phase control of a rhythm to a regularly occurring environmental cycle (usually ~24 h)

ORGANIZATION OF THE CIRCADIAN SYSTEM

For biological clocks to be effective, they must accurately keep time and adjust to environmental signals. In an organized circadian system, this requires SCN control of peripheral oscillators, and loss of the SCN results in peripheral circadian clocks that become desynchronized (Yoo et al. 2004). However, tissue-specific gene expression patterns are likely to be regulated by both "local" as well as central mechanisms. This concept was elegantly demonstrated through genetic disruption of the

Figure 2

Network and autonomous properties of suprachiasmatic nucleus (SCN) neurons. Network properties of the SCN can compensate for genetic defects affecting rhythmicity at the cell-autonomous level. (*a*) Bioluminescence images of a *Cry1*$^{-/-}$ SCN in organotypic slice culture. Note the stable, synchronized oscillations. Numbers indicate hours after start of imaging; 3V indicates the third ventricle. (*b*) Bioluminescence images of dissociated individual *Cry1*$^{-/-}$ SCN neurons showing cell-autonomous, largely arrhythmic patterns of high bioluminescence intensity. (*c*,*d*) Heat-map representations of bioluminescence intensity of individual *Cry1*$^{-/-}$ neurons in an (*a*) SCN slice and (*b*) dispersed culture. Values above and below the mean are shown in red and green, respectively, for 40 SCN neurons in each condition. (*e*,*f*) Ten single SCN neuron rhythms from (*e*) wild-type and (*f*) *Cry1*$^{-/-}$ mice. Imaging began immediately following a media change at day 0. Dissociated *Cry1*$^{-/-}$ SCN neurons are largely arrhythmic, whereas dissociated wild-type cells are rhythmic. By contrast, in organotypic slice cultures, both wild-type and *Cry1*$^{-/-}$ SCN cells are robustly rhythmic and tightly synchronized. Figure and legend adapted and reprinted from Liu et al. (2007a), with permission from Elsevier.

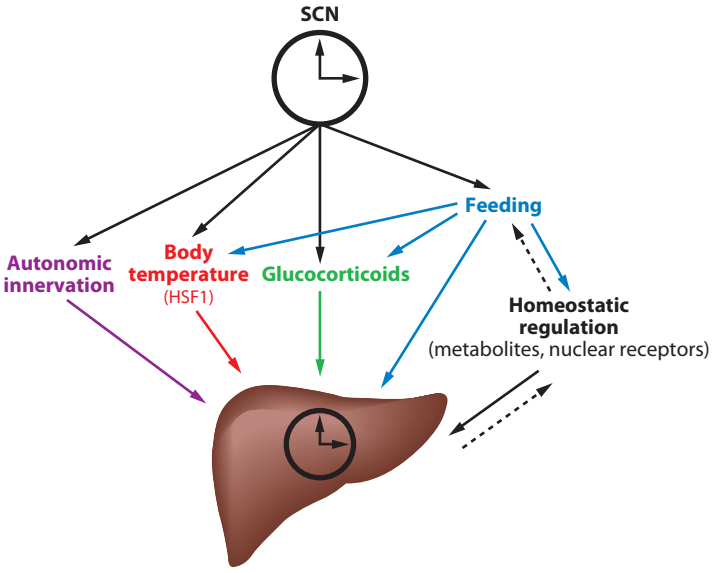

Figure 3

Pathways of peripheral clock entrainment. The master circadian pacemaker within the suprachiasmatic nucleus (SCN) relays temporal information to peripheral oscillators through autonomic innervation, body temperature, humoral signals (such as glucocorticoids), and feeding-related cues. Independent of the SCN, local signaling pathways can also affect peripheral oscillators.

circadian clock mechanism specifically in the hepatocytes of mice, while leaving the circadian clock intact in the SCN and other cell types throughout the body (Kornmann et al. 2007). Microarray analysis of mRNAs in the livers from these mice demonstrated that the disruption of the circadian molecular feedback loop specifically within the liver results in arrhythmicity of most hepatic transcripts. Thus, most circadian oscillations of hepatic function rely on an intact liver clock. However, a subset of transcripts, including the core clock component *Per2*, continued to cycle robustly even in the absence of a functional liver clock. In livers maintained in explant culture, rhythms in *Per2* transcription were observed in livers with intact clocks but were absent in livers with inactivated clocks. Thus, rhythmic gene expression can be driven by both local intracellular clocks and by extracellular systemic cues.

What are these systemic cues? The photically entrained SCN is thought to convey signals to light-insensitive peripheral clocks to synchronize these systems, and SCN transplant studies (Ralph et al. 1990, Silver et al. 1996) and parabiosis experiments in mice (Guo et al. 2005) have demonstrated that both humoral and nonhumoral pathways are important for SCN coordination of circadian output rhythms. In addition, complex feedback loops link the circadian clock with rhythmic metabolic networks, integrating these systems in a light-independent manner. Circadian control of metabolism occurs at the central (SCN) as well as local levels and involves clocks within a number of peripheral tissues including the liver, pancreas, skeletal muscle, intestine, and adipose tissue (for a review, see Bass & Takahashi 2010, Green et al. 2008). This intimate relationship between clocks and metabolism is an example of how the circadian "system" is integrated with, and influenced by, the physiology that is under its control. Therefore, organization of the circadian system requires a combination of (*a*) autonomic innervation of peripheral tissues, (*b*) endocrine signaling, (*c*) temperature, and (*d*) local signals (**Figure 3**).

Neural Control of Peripheral Oscillators: The Autonomic Nervous System

The SCN controls peripheral oscillators through both sympathetic and parasympathetic pathways (Kalsbeek et al. 2010, Ueyama et al. 1999). SCN projections through the paraventricular nucleus–superior cervical ganglia (PVN-SCG) pathway provide the dominant entraining signal for the submandibular salivary glands (Ueyama et al. 1999, Vujovic et al. 2008). Sympathetic innervation from the SCN to the PVN to the liver results in daily rhythms of plasma glucose, presumably by directly influencing the rhythm of hepatic gluconeogenesis (Cailotto et al. 2005, Kalsbeek et al. 2004).

Autonomic pathways from the SCN relay photic information to oscillators in the adrenal gland and liver (Buijs et al. 1999, Cailotto et al. 2009, Ishida et al. 2005). Sympathetic innervation also modulates the sensitivity of the adrenal to adrenocorticotropic hormone (ACTH) and

Annu. Rev. Neurosci. 2012.35:445-462. Downloaded from www.annualreviews.org
by Stanford University - Main Campus - Green Library on 07/10/12. For personal use only.

directly influences glucocorticoid release (Buijs et al. 1999, Kalsbeek et al. 2010, Kaneko et al. 1981). Oscillators in both the adrenal cortex and medulla respond to neural inputs emanating from the SCN (Buijs et al. 1999, Mahoney et al. 2010). The adrenal clock is of particular interest given the strong case for glucocorticoids as a humoral entraining signal for peripheral clocks.

Hormonal Control of Peripheral Oscillators

Although a number of hormones may have roles in mammalian circadian organization, glucocorticoids have received the most attention. Rhythmic glucocorticoids result both from the sympathetic inputs discussed above and from an underlying rhythm of corticotropin releasing hormone (CRH) and ACTH function (Kaneko et al. 1980, Kaneko et al. 1981). The adrenal clock also provides temporal control of sensitivity to ACTH-induced glucocorticoid release (Oster et al. 2006).

The demonstration that dexamethasone (a glucocorticoid analog) could shift the phase of peripheral tissues in vivo (Balsalobre et al. 2000) provided the first definitive evidence that glucocorticoids were entraining signals for peripheral oscillators. Dexamethasone was initially shown to shift the phase of clock gene expression in the liver, kidney, and heart as well as cultured fibroblasts. What provides glucocorticoid input into the clock at the local level? Glucocorticoid-response elements exist in the regulatory regions of the core clock genes, *Bmal1*, *Cry1*, *Per1* (Reddy et al. 2007, Yamamoto et al. 2005), and *Per2* (So et al. 2009). These glucocorticoid-response elements may lead to the transcriptional activation of a number of clock genes and clock-controlled genes by glucocorticoids.

Glucocorticoids can synchronize circadian expression of much of the oscillatory component of the liver transcriptome in SCN-lesioned mice (Reddy et al. 2007). This is accomplished, in part, through activation of the nuclear receptor (and hepatic transcription factor) HNF4α. HNF4α is responsive to glucocorticoids (Reddy et al. 2007), contains E-boxes, which may allow for transcriptional control by CLOCK:BMAL1 (Reddy et al. 2007), and can interact with PER2 (Schmutz et al. 2010). Other metabolically relevant nuclear receptors, including peroxisome proliferator-activated receptor (PPAR)α, also respond to glucocorticoids (Lemberger et al. 1994). Nuclear receptor activation by clock components and glucocorticoids provides another point of circadian input to metabolic pathways as described below.

PPAR: peroxisome proliferator-activated receptor

HSF1: heat shock factor 1

Temperature

In most organisms, temperature is a powerful entraining agent for circadian rhythms. However, in mammals, external temperature cycles are very weak entraining agents (Refinetti 2010); this has been attributed to the fact that homeotherms regulate their body temperature and can defend their body temperature against environmental fluctuations. It has long been known that body temperature is circadian and the rhythm is driven by the SCN. Peripheral oscillators, including fibroblasts, liver, kidney, and lung, are exquisitely sensitive to temperature changes (Abraham et al. 2010, Brown et al. 2002, Buhr et al. 2010, Kornmann et al. 2007). These oscillators can be strongly reset by low-amplitude temperature pulses that mimic the range of circadian variation, and temperature profiles that match circadian body temperature rhythms strongly entrain peripheral clocks (Brown et al. 2002, Buhr et al. 2010). However, as described above, the SCN is resistant to temperature cycles in the circadian range. Because of this system design, the SCN is ideally situated to utilize circadian temperature cycles as a universal entraining signal for peripheral oscillators. The influence of temperature on peripheral oscillators likely occurs through the transcription factor heat shock factor 1 (HSF1). HSF1 transcriptional activity oscillates with a circadian rhythm in the liver and can be driven by temperature cycles (Reinke et al. 2008). HSF1 inhibitors block temperature-induced resetting in extra-SCN

by Stanford University - Main Campus - Green Library on 07/10/12. For personal use only.

NAD: nicotinamide adenine dinucleotide

oscillators (Buhr et al. 2010). Because HSF1 is influenced by a wide range of signaling pathways in the cell (Akerfelt et al. 2010), temperature and HSF1 may form a final common pathway for the integration of resetting signals in peripheral clocks.

Behavioral and Homeostatic Regulation: Local Cues Feed Back into the Clock

In addition to controlling hormone secretion and body temperature directly, the SCN coordinates rhythms in behavioral processes, such as locomotor activity and feeding, which can influence endocrine function and body temperature. These behaviors, feeding in particular, can regulate peripheral clocks at the local level, modulating local signaling pathways and metabolic processes. Homeostatic signaling pathways also affect peripheral clocks and their function, allowing for extra SCN control of circadian processes. Studies in which mealtime has been experimentally manipulated to occur antiphase to the normal SCN-driven feeding rhythm have attempted to elucidate local mechanisms for controlling clocks in peripheral tissues.

The liver clock, unlike the SCN, is particularly sensitive to resetting by feeding. Hepatic rhythms of clock gene and protein expression rapidly shift their phase to follow the timing of a scheduled meal (Damiola et al. 2000, Stokkan et al. 2001). Similarly, livers of *Cry1/Cry2*-null mice display rhythms in many transcripts (including a number of transcripts involved in metabolic processes) when fed in regular 24-h intervals (Vollmers et al. 2009). Feeding appears to result in cues that bypass the core circadian feedback loop to drive these rhythms. These cues may include feeding-induced changes in temperature and HSF1 activity (Kornmann et al. 2007) or activation of other metabolically sensitive pathways.

A number of local mediators of both core clock components and clock-controlled rhythmic transcripts have been identified, and can respond to SCN-driven inputs as well as local signals related to homeostasis and metabolic state. These mediators include members of the nuclear receptor family of transcription factors, many of which exhibit circadian rhythms of transcription within the liver and other metabolically relevant tissues (Yang et al. 2006). These rhythmic nuclear receptors regulate transcription of downstream metabolic pathways. Among the rhythmic nuclear receptors are PPARs and members of the REV-ERB and ROR families. As described above, RORα and REV-ERBα participate directly in the clock mechanism by regulating *Bmal1* transcription (Preitner et al. 2002, Sato et al. 2004), but they are also important for many aspects of metabolic regulation. Similar to REV-ERBs and RORs, many of the other rhythmic nuclear receptors are regulators of clock function, providing a mechanism by which signals of metabolic status can influence rhythmicity. Glucocorticoid receptors, as discussed above, induce transcription of *Per* and potentially a number of other clock and clock-controlled genes (Reddy et al. 2007, So et al. 2009, Yamamoto et al. 2005). PPARα, which responds to lipid status and glucocorticoids, may also regulate *Bmal1* transcription (Canaple et al. 2006).

PPARγ coactivator-1α (PGC-1α, a transcriptional coactivator) provides a link between the clock and changes in metabolic status. PGC-1α is critical for adaptive responses to nutritional and metabolic state, particularly following fasting (reviewed in Lin et al. 2005). PGC-1α is rhythmic and activates expression of *Bmal1* and *Rev-erbα* through coactivation of RORs (Liu et al. 2007b). PGC-1α-null mice display disruptions in a number of circadian outputs including locomotor activity, oxygen consumption rate, and expression of both clock and metabolic genes (Liu et al. 2007b). PGC-1α also interacts with SIRTUIN 1 (SIRT1), a nicotinamide adenine dinucleotide (NAD)-dependent histone deacetylase (Rodgers et al. 2005).

Another mechanism by which metabolic signals can feed into the clock is through the adenosine monophosphate-activated protein kinase (AMPK) (Bass & Takahashi 2010). This kinase is a central mediator of metabolic

Annu. Rev. Neurosci. 2012.35:445-462. Downloaded from www.annualreviews.org
by Stanford University - Main Campus - Green Library on 07/10/12. For personal use only.

signals. AMPK activity is robustly rhythmic in mouse liver and is regulated by nutrient status, as reflected in the ratio of AMP to ATP. Active AMPK directly regulates the central clock mechanism by phosphorylating and destabilizing the clock component CRY1 (Lamia et al. 2009).

Cellular redox state can also serve as a mechanism by which the metabolic status of the cell can impact the circadian system. NAD levels exhibit circadian oscillations in the liver, likely owing to transcriptional regulation of nicotinamide phosphoribosyltransferase (*Nampt*, encoding the rate-limiting enzyme in the NAD^+ salvage pathway) by CLOCK:BMAL1 (Nakahata et al. 2009, Ramsey et al. 2009). NAD levels also vary with cellular redox state as a consequence of metabolic changes, which, in turn, can directly impact clock function. The ratio of NAD^+ to NADH influences binding of NPAS2:BMAL1 and CLOCK:BMAL1 to DNA in vitro, suggesting one way in which NAD could interact with clock components (Rutter et al. 2001).

NAD^+-dependent SIRT1 also displays daily oscillations and feeds back onto the circadian clock. SIRT1 forms a complex with CLOCK:BMAL1, leading to the deacetylation of PER2 (Asher et al. 2008) and BMAL1 (Nakahata et al. 2008). SIRT1 also suppresses CLOCK:BMAL1-mediated transcription, resulting in decreased expression of *Per2* (Nakahata et al. 2008, Ramsey et al. 2009) and the clock-controlled gene *Dbp* (Nakahata et al. 2008).

Another molecule with NAD^+-sensitive activity, poly(ADP-ribose) polymerase 1 (PARP-1), was recently shown to interact with the circadian clock (Asher et al. 2010). PARP-1 activity is rhythmic in the liver, and this rhythm persists even in the absence of a functional hepatic circadian clock. The rhythm of PARP-1 activity can be entrained by scheduled meals, however, suggesting that the circadian activity of PARP-1 is driven by feeding-related cues. PARP-1 interacts with CLOCK:BMAL1 in a rhythmic fashion and inhibits DNA binding by the CLOCK:BMAL1 complex. PARP-1 also polyADP-ribosylates CLOCK and appears to temporally regulate the interaction of CLOCK:BMAL1 with PER2 and CRYs. The circadian regulation of PARP-1 by feeding, and subsequent consequences for the circadian clock, are likely not entirely mediated through NAD^+. Regardless of the mechanism, PARP-1 provides another way for metabolic signals to influence timekeeping by the core molecular clock.

OTHER OSCILLATORS: FOOD AND DRUGS

The circadian system consists of a web of interconnected oscillators and feedback loops. The core molecular clock within cells keeps time and responds to cues from the SCN (through neural, hormonal, and activity-driven pathways) as well as signals from the local cellular environment. These cell- and tissue-level clocks result in rhythms of physiologically relevant outputs, including glucose production, fat storage, and hormone production. These outputs, in turn, become circadian time-keeping cues relayed to other clocks throughout the body, likely ultimately feeding back to the central nervous system and the SCN. Under normal circumstances, the SCN maintains temporal organization of body temperature, activity, feeding, and neural output rhythms. This keeps local and systemic circadian signals aligned. In the absence of the SCN, however, the system becomes disorganized. Activity is nonrhythmic and peripheral tissues and cells drift out of phase with one another. There are two striking exceptions to this phenomenon. Scheduled, restricted feeding and chronic administration of methamphetamine, a psychostimulant drug of abuse, are both capable of organizing the circadian outputs in the absence of the SCN.

The Food-Entrainable Oscillator

It is not surprising that food and food-related cues are salient for many biological processes, including circadian rhythms. The ability of animals to anticipate food availability is well

Annu. Rev. Neurosci. 2012.35:445-462. Downloaded from www.annualreviews.org
by Stanford University - Main Campus - Green Library on 07/10/12. For personal use only.

established and persists even when food is provided at a time that is out of phase with the animal's normal feeding time (Richter 1922, Stephan et al. 1979). When food is temporally restricted to the daytime (the normal rest period), nocturnal rodents will anticipate the arrival of the meal with an increase in activity; if the timing of that meal is shifted, rats will display transients, gradually shifting their food-anticipatory activity bout each day until it again precedes the start of food availability.

In animals with lesions of the SCN, temporal food restriction will induce circadian rhythmicity of locomotor behavior (Stephan et al. 1979) and an accompanying temperature rhythm (Krieger et al. 1977). Food-anticipatory activity persists on days of total food deprivation, demonstrating that these cycles are not merely an hourglass phenomenon but are driven by an underlying oscillator (Stephan 2002). This food-entrainable oscillator (FEO) can take on pacemaking functions—organizing rhythms of activity, body temperature, and peripheral tissues in SCN-lesioned animals. Peripheral tissues from both SCN-intact and SCN-ablated mice are sensitive to temporally restricted feeding. In SCN-intact animals, phase desynchrony among peripheral oscillators can occur: Some tissues remain in phase with the (food-unaffected) SCN, and some follow the phase of food availability (Damiola et al. 2000, Pezuk et al. 2010). Cues related to the meal must be the dominant entraining signals in this latter group of tissues. In SCN-lesioned mice, food entrainment organizes rhythms throughout the periphery, and stable phase relationships are observed among tissues (Hara et al. 2001, Pezuk et al. 2010).

Interestingly, the FEO does not appear to require a functional molecular clock, as *Bmal1*$^{-/-}$ and *Per1/Per2*$^{-/-}$ mice can entrain to restricted feeding (Pendergast et al. 2009, Storch & Weitz 2009). The mechanism by which food drives oscillatory behavior throughout the organism is unknown. It is possible that the FEO exploits some of the same pathways used by the SCN, such as hormone- and temperature-dependent cues, to organize peripheral tissues. The locus (or loci) of the FEO is also unknown. A number of structures, including the olfactory bulbs (Davidson et al. 2001), the ventromedial hypothalamus (Mistlberger & Rechtschaffen 1984), the paraventricular thalamic nucleus (Landry et al. 2007), and a large portion of the digestive system (Davidson et al. 2003), have been ruled out.

The dorsomedial hypothalamus (DMH) has received considerable attention for its role in food entrainment. Data supporting a role for the DMH in the generation of food-anticipatory circadian activity are controversial (Gooley et al. 2006, Landry et al. 2006, Moriya et al. 2009), and the DMH may not be essential for the expression of the FEO (Landry et al. 2006, Moriya et al. 2009). The DMH does, however, interact with the SCN under conditions of food restriction and may influence the strength of the FEO output, particularly in SCN-intact animals (Acosta-Galvan et al. 2011).

The Methamphetamine-Sensitive Circadian Oscillator

Chronic or scheduled methamphetamine treatment affects circadian outputs in a manner similar to food restriction (Honma & Honma 2009). Methamphetamine, provided in the drinking water of rats and mice, is capable of driving circadian rhythms of locomotor behavior in the absence of the SCN (Honma et al. 1987, Tataroglu et al. 2006). In SCN-intact animals, this appears as a lengthening of the free-running period of locomotor activity, and in some cases, two activity components (relatively coordinated with each other) are observed. Much like the FEO, these rhythms persist when the stimulus (in this case, methamphetamine) is withdrawn (Tataroglu et al. 2006) as well as in the absence of a functional molecular clock (Honma et al. 2008, Mohawk et al. 2009). The methamphetamine-sensitive circadian oscillator (MASCO) is capable of functioning as a pacemaker driving rhythms in locomotor activity, body temperature, endocrine function, and the oscillators of peripheral

tissues (Honma et al. 1988, Pezuk et al. 2010). In the presence of the SCN, methamphetamine results in desynchrony among internal oscillators, as some follow the SCN and some follow the presumed phase of the MASCO (Pezuk et al. 2010). When the SCN is ablated, however, the MASCO organizes oscillators in tissues throughout the organism, resulting in a coordinated system (Pezuk et al. 2010).

The site of the MASCO is also unknown. It is possible that the FEO and MASCO share an anatomical and mechanistic basis, or, indeed, that they represent a single oscillator. Research focused on understanding how the MASCO and FEO relay circadian information to peripheral tissues will likely uncover novel (or underappreciated) mechanisms that control circadian rhythms. The role of these oscillators in the absence of food restriction and methamphetamine must also be determined. It is unlikely that these oscillators are dormant under normal conditions; instead, the FEO, MASCO, and SCN probably cooperate in a hierarchically organized, perhaps necessarily redundant, timing network.

SUMMARY

It is now clear that there is feedback at nearly every level of the circadian system. "Outputs" such as body temperature and feeding become inputs to other oscillators and are capable of influencing the core molecular clockwork, generating complex interconnectivity between the circadian system and the biological outputs it controls. Reciprocity between the circadian and metabolic systems makes it likely that perturbations in one system affect the other. This idea is supported both genetically—circadian mutants have metabolic phenotypes—and environmentally—nutrient intake can modulate circadian rhythms (Bass & Takahashi 2010). In recent years, considerable progress has been made in unraveling the connections between the circadian clock and metabolism. The role of circadian clocks in governing many other physiological systems has been established, but is far less well characterized.

We still know very little about how oscillators and timing cues are integrated at the local and organismal levels to coordinate the circadian architecture of the animal. Peripheral clocks must balance (sometimes conflicting) inputs arising from the SCN with those signaling local cellular and metabolic state. Moreover, recent work has revealed that the cell-autonomous oscillator, which normally lies at the foundation of the circadian clockwork, is not absolutely crucial for the expression of rhythms by other components of the system. Within the SCN, coupling among individual neurons gives rise to a heterogeneous, yet elegantly organized, robust oscillatory network, which can overcome impaired rhythmicity at the cellular level (Ko et al. 2010, Liu et al. 2007a). Food- and drug-sensitive oscillators (FEO, MASCO) can influence circadian rhythms and drive rhythmic outputs in the absence of the core molecular clock mechanism (Honma et al. 2008, Mohawk et al. 2009, Pendergast et al. 2009, Storch & Weitz 2009). The ability of rhythmic circadian outputs to persist in the absence of the SCN necessitates that any model of the circadian network include alternative mechanisms for controlling circadian rhythms at the cell, tissue, and organism levels.

ORIGINAL ARTICLE

Childhood Adversities and Adult Psychiatric Disorders in the National Comorbidity Survey Replication I

Associations With First Onset of DSM-IV *Disorders*

Jennifer Greif Green, PhD; Katie A. McLaughlin, PhD; Patricia A. Berglund, MBA; Michael J. Gruber, MS; Nancy A. Sampson, BA; Alan M. Zaslavsky, PhD; Ronald C. Kessler, PhD

Context: Although significant associations of childhood adversities (CAs) with adult mental disorders have been documented consistently in epidemiological surveys, these studies generally have examined only 1 CA per study. Because CAs are highly clustered, this approach results in overestimating the importance of individual CAs. Multivariate CA studies have been based on insufficiently complex models.

Objective: To examine the joint associations of 12 retrospectively reported CAs with the first onset of *DSM-IV* disorders in the National Comorbidity Survey Replication using substantively complex multivariate models.

Design: Cross-sectional community survey with retrospective reports of CAs and lifetime *DSM-IV* disorders.

Setting: Household population in the United States.

Participants: Nationally representative sample of 9282 adults.

Main Outcome Measures: Lifetime prevalences of 20 *DSM-IV* anxiety, mood, disruptive behavior, and substance use disorders assessed using the Composite International Diagnostic Interview.

Results: The CAs studied were highly prevalent and intercorrelated. The CAs in a maladaptive family functioning (MFF) cluster (parental mental illness, substance abuse disorder, and criminality; family violence; physical abuse; sexual abuse; and neglect) were the strongest correlates of disorder onset. The best-fitting model included terms for each type of CA, number of MFF CAs, and number of other CAs. Multiple MFF CAs had significant subadditive associations with disorder onset. Little specificity was found for particular CAs with particular disorders. Associations declined in magnitude with life course stage and number of previous lifetime disorders but increased with length of recall. Simulations suggest that CAs are associated with 44.6% of all childhood-onset disorders and with 25.9% to 32.0% of later-onset disorders.

Conclusions: The fact that associations increased with length of recall raises the possibility of recall bias inflating estimates. Even considering this, the results suggest that CAs have powerful and often subadditive associations with the onset of many types of largely primary mental disorders throughout the life course.

SIGNIFICANT ASSOCIATIONS between retrospectively reported childhood adversities (CAs) and adult illness have been documented in numerous studies.[1,2] The first such studies focused on only a single CA, such as parental death or neglect,[3,4] and 1 mental disorder, most often depression.[5,6] Subsequent studies showed that retrospectively reported CAs are often highly clustered,[7,8] requiring examination of multiple CAs to avoid overestimating associations involving particular CAs.[2,9,10] These studies also found that CAs are often nonspecific in their associations with many different mental disorders,[10-12] making it useful to examine multiple outcomes to avoid overly narrow interpretations.

See also pages 111 and 124

Subsequent studies[13-15] created summary CA scales and documented dose-response relationships with adult outcomes. However, such indices implicitly assumed that each CA has the same effect and that joint effects are additive. These assumptions are almost certainly incorrect.[16] Indeed, a preliminary examination of these assumptions in the National Comorbidity Survey (NCS)[17] showed that some CAs have stronger associations with

Downloaded From: http://archpsyc.jamanetwork.com/ by a University of Alabama-Birmingham User on 07/25/2015

adult outcomes than do others and that joint associations are nonadditive.[10] That study also found that these associations sometimes attenuate with age, a specification generally, but not always,[12,18] ignored in subsequent studies.

The present study builds on these earlier NCS findings by analyzing the CAs assessed in the NCS Replication (NCS-R).[19] Associations between retrospectively reported CAs and mental disorders can be upwardly biased owing to recall failure, nevertheless, it is useful to examine associations based on such retrospective data because they provide upper estimates that avoid the problem of downward bias due to systematic sample attrition in estimates based on long-term prospective data. We examine associations of CAs with the first onset of diverse *DSM-IV* disorders based on several competing multivariate models. A companion study[20] examines associations of CAs with lifetime persistence of the same disorders.

METHODS

SAMPLE

The NCS-R is a face-to-face survey of English-speaking adults performed between February 5, 2001, and April 7, 2003, in a multistage clustered area probability sample of the US household population.[19] The response rate was 70.9%. Recruitment began with a letter and a study fact brochure followed by in-person interviewer visits to explain study aims and procedures before obtaining informed consent. Respondents were paid $50 for participation. Recruitment and consent procedures were approved by the human subjects committees of Harvard Medical School, Boston, Massachusetts, and the University of Michigan, Ann Arbor.

The survey was administered in 2 parts. Part I included a core diagnostic assessment and was administered to all the respondents (n=9282). Part II, which was generally administered on the same occasion as part I, included questions about correlates and additional disorders administered to all part I respondents who met lifetime criteria for any part I disorder plus a probability subsample of other part I respondents (n=5692). The part I sample was weighted to adjust for differential probabilities of selection and intensity of recruitment effort in hard-to-recruit cases. The part II sample, the focus of the present study, was additionally weighted for the lower selection probabilities of part I respondents without a mental disorder. A final weight adjusted the sample to match the 2000 census population on the cross-classification of numerous geographic and sociodemographic variables. All the analyses used these weights. As a result, the sociodemographic characteristics of the weighted part II sample closely match those of the population (eg, 42% female, 71% non-Hispanic white, 24% aged 18-29 years, and 21% ≥60 years old). More detailed information on NCS-R sampling, design, weighting, and sociodemographic distribution is reported elsewhere.[21]

DIAGNOSTIC ASSESSMENT

The NCS-R lifetime diagnoses are based on the World Health Organization Composite International Diagnostic Interview (CIDI),[22] a fully structured, lay-administered interview that generates diagnoses according to the definitions and criteria of the *Internaaational Classification of Diseases, 10th Revision* and the *DSM-IV*. The *DSM-IV* criteria are used herein. The lifetime diagnoses include 4 broad classes of 20 specific disorders: mood disorders (major depressive disorder, dysthymic disorder, bipolar I disorder, bipolar II disorder, and subthreshold bipolar disorder), anxiety disorders (panic disorder, agoraphobia without a history of panic disorder, generalized anxiety disorder, specific phobia, social phobia, posttraumatic stress disorder, and separation anxiety disorder), disruptive behavior disorders (intermittent explosive disorder, attention-deficit/hyperactivity disorder, oppositional-defiant disorder, and conduct disorder), and substance use disorders (alcohol abuse, alcohol dependence with abuse, drug abuse, and drug dependence with abuse). Diagnostic hierarchy rules and organic exclusion rules were used in making diagnoses. The *DSM-IV*/CIDI disorder prevalence estimates in sociodemographic subsamples are reported elsewhere (http://www.hcp.med.harvard.edu/ncs). An NCS clinical reappraisal study[23] found generally good concordance between diagnoses based on the CIDI and those based on blinded clinical reinterviews using the Structured Clinical Interview for *DSM-IV*.[24]

The CIDI assessed age at onset of the disorder retrospectively. Based on evidence that retrospective age-at-onset reports are often erroneous,[25] a special question sequence was used to improve the accuracy of reporting. This began with questions designed to emphasize the importance of accurate responses: "Can you remember your exact age the *very first time* [emphasis in original] when you had [the symptom/the syndrome]?" Respondents who answered "no" were then probed for a bound of uncertainty by asking the earliest age at which they could clearly remember having the disorder. Onset was set at the upper end of the bound of uncertainty. Experimental research[26] has shown that this approach yields more plausible age-at-onset distributions than do standard age-at-onset questions.

CHILDHOOD ADVERSITIES

Twelve dichotomous CAs occurring before age 18 years were assessed in the NCS-R. The selection of CAs was based on a review of the literature. These CAs include 3 types of interpersonal loss (parental death, parental divorce, and other separation from parents or caregivers), 4 types of parental maladjustment (mental illness, substance abuse, criminality, and violence), 3 types of maltreatment (physical abuse, sexual abuse, and neglect), and 2 other CAs (life-threatening childhood physical illness in the respondent and extreme childhood family economic adversity). The measures of parental death, divorce, and other separation (eg, respondent placed in foster care) focus only on the biological parents, not on stepparents or other caregivers. Respondents who were born to a single mother and never experienced any further disruption of this parenting arrangement were coded as not experiencing any parental separation. We did not include information about the number of caregiver disruptions (eg, multiple divorces) or separations (eg, multiple foster care placements) but rather coded respondents dichotomously as having any vs no such disruptions because the rarity of multiple disruptions made estimates of dose-response relationships unstable.

Parental criminality, family economic adversity, and sexual abuse were assessed using a short question series developed for the baseline NCS.[10] Parental criminality was assessed using questions about whether a parent either engaged in criminal activities, such as burglary or selling stolen property, or was ever arrested for criminal activity. Economic adversity was assessed using questions about whether the family received welfare or other government assistance and whether the family often lacked enough money to pay for the basic necessities of living. Sexual abuse was assessed using questions about repeated fondling, attempted rape, and rape. Parental mental

illness (major depression, generalized anxiety disorder, and prior to panic disorder) and substance abuse were assessed using the Family History Research Diagnostic Criteria interview[27] and its extensions.[28] Family violence and physical abuse of the respondent by parents were assessed using a modified version of the Conflict Tactics Scales.[29] Neglect was assessed using questions used in studies of child welfare about the frequency of not having adequate food, clothing, or medical care; having inadequate supervision; and having to do age-inappropriate chores.[30] Life-threatening physical illness was assessed using a standard chronic conditions checklist.[31]

ANALYSIS METHODS

Tetrachoric factor analysis (promax rotation) was used to examine intercorrelations among CAs. Associations of CAs with lifetime disorders were estimated using discrete-time survival analysis, with person-years as the unit of analysis,[32] controlling for respondent age at interview, sex, race/ethnicity (non-Hispanic white, non-Hispanic black, Hispanic, and other), and other *DSM-IV*/CIDI disorders with onset before the age at onset of the disorder under investigation and before age 18 years. The controls for early-onset disorders were included to adjust for the associations of CAs with temporally secondary disorders through earlier-onset disorders that affected secondary disorders. Person-years began at age 4 years, the youngest age evaluated for possible disorder onset. Person-years were coded "0" on the dependent variables until the age at onset and "1" at the year of onset and were censored after the year of onset. Several multivariate models were estimated, with each including dummy predictor variables for CAs plus controls. The first model was additive; that is, it included a separate predictor variable for each of the 12 CAs without interaction terms. The second multivariate model included predictor variables for number of CAs without variables for types of CAs experienced. A third model included 12 predictors for type of CA and additional predictors for number of CAs, with the latter starting at exactly 2 rather than 1 because the variable for exactly 1 CA was perfectly predicted by the 12 dummy variables for the individual CAs. A variant of this third model distinguished between 2 types of CAs as described in the "Associations of CAs With the First Onset of *DSM-IV*/CIDI Disorders" subsection. Another variant included interactions between types of CAs and number of CAs. Finally, we considered more complex, inherently nonlinear models, but these did not improve on the fit of the simpler models and are consequently not discussed herein.

The Akaike information criterion[33] was used to select the best multivariate model for the overall data array (ie, the consolidated data file that stacked the 20 separate disorder-specific person-year files and included 19 dummy predictor variables to distinguish among these files, thereby forcing the estimated slopes of disorders on CAs to be constant across disorders). This best-fitting model was then estimated again in subsamples defined by disorder, class of disorder (mood, anxiety, disruptive behavior, and substance use disorders), life course stage, and the conjunction of life course stage with class of disorder. Survival coefficients and their standard errors were exponentiated and are reported as odds ratios (ORs) and 95% confidence intervals, respectively.

The population-attributable risk proportion (PARP) of the outcomes was computed for the best-fitting model. The PARP is the proportion of observed outcomes that would have been prevented in the absence of CAs if the ORs were due to causal effects of CAs.[34] In the more realistic case in which the associations of CAs with outcomes are partly due to common causes, the PARP reflects overall associations. All of the PARPs were calculated using simulation methods to generate individual-level predicted probabilities of the outcome disorders from the coefficients in the best-fitting model with and without coefficients for CAs. The PARP is 1 minus the ratio of the predicted prevalence estimates in the 2 specifications. The PARP for a pooled data set is the average PARP across all disorders included in the calculation based on a constant model across disorders.

All statistical significance tests were evaluated using 2-sided tests ($P < .05$). Because the NCS-R data are clustered and weighted, the design-based Taylor series method[35] implemented in the SUDAAN software system[36] was used to estimate standard errors of ORs.

RESULTS

PREVALENCE AND CO-OCCURRENCE OF CAs

Approximately 53.4% of NCS-R respondents reported having at least 1 CA (**Table 1**). The most common CAs were parental divorce (17.5%), family violence (14.0%), family economic adversity (10.6%), and parental mental illness (10.3%). Multiple CAs were the norm in respondents with each CA, from 51.2% in those with death of a parent to 95.1% in those with parental neglect; there were a mean of 3.2 CAs in respondents with more than 1 CA.

Most tetrachoric correlations between pairs of CAs (94%) are positive. (Detailed results are available on request from the corresponding author.) Negative values are small (range, –0.09 to –0.01). Positive values have a median of 0.11 and an interquartile range (25th-75th percentiles) of 0.04 to 0.19. Factor analysis found 3 meaningful factors (Table 1). Most CAs have significant loadings on the first factor of maladaptive family functioning (MFF) (eg, parental substance abuse, criminality, domestic violence, and abuse and neglect), with factor loadings of 0.32 to 0.67. The second factor represents parental death and other loss with associated economic adversity (factor loadings, 0.50-0.67). The third factor represents parental divorce with associated economic adversity (factor loadings, 0.48-0.83). The CAs in factor 1 are referred to herein as MFF CAs and the remaining CAs as other CAs.

ASSOCIATIONS OF CAs WITH THE FIRST ONSET OF *DSM-IV*/CIDI DISORDERS

In the bivariate models (ie, only 1 CA considered at a time) of the pooled associations of CAs with the first onset of the 20 *DSM-IV*/CIDI disorders, all but 1 CA (parental death) was significant, with ORs of 1.5 to 1.9 for MFF CAs and 1.0 to 1.5 for other CAs (**Table 2**). The ORs are generally smaller in the additive multivariate model, with 8 CAs significant and ORs of 1.0 to 1.4 for MFF CAs and 1.0 to 1.3 for other CAs. The χ^2 test for associations of all CAs is significant ($\chi^2_{12} = 884.5$, $P < .001$), although the ORs are substantively modest. We can reject the hypothesis that the ORs are the same for all CAs ($\chi^2_{11} = 286.6$, $P < .001$).

The multivariate model that considers only number rather than type of CAs shows generally increasing ORs with number of CAs, from 1.3 for 1 CA (compared with

[c] Factors 2 and 3 are combined and refer to other CAs.

respondents who had no CAs) to highs of 3.4 for 6 CAs and 3.2 for 7 or more CAs. The χ^2 test for the joint associations is significant (χ^2_7=822.0, $P<.001$). The model that includes measures of types of CAs and number of CAs fits the data better than the previous models in terms of Akaike information criterion, as indicated by the types-of-CA measures being significant after controlling for number of CAs (χ^2_{12}=86.9, $P<.001$) and the number of CAs measures being significant after controlling for types (χ^2_6=63.7, $P<.001$). (Detailed results of model fitting are available on request from the author.) The hypothesis that the ORs are the same for all types of CAs can be rejected (χ^2_{11}=60.0, $P<.001$). The MFF CAs consistently have higher ORs than do other CAs. The ORs associated with types are mostly higher than in the additive model, indicating that the additivity assumption led to a downward bias in the estimated associations of individual CAs with the outcome. The reason for this is that the ORs associated with number of CAs in the more complex model are for the most part less than 1.0 and become increasingly smaller as number of CAs increases. This means that although the odds of disorder onset increase with increasing number of CAs, they increase at a significantly decreasing rate.

We also evaluated more complex models but found that they generally did not fit as well as the model with types and number of CAs. One refinement did improve fit, although by distinguishing number of MFF CAs from number of other CAs. The significant subadditive interactions associated with number of CAs are found for MFF CAs (χ^2_6=61.7, $P<.001$) but not for other CAs (χ^2_3=5.2, $P=.16$). (The test had only 3 *df* because no respondents had all 5 MFF CAs.) This was the model used in subsequent disaggregated analyses.

DIFFERENTIAL ASSOCIATIONS BY CLASS OF *DSM-IV*/CIDI DISORDER

Disaggregation shows that CAs are significantly associated with the first onset of each class of disorders (mood, anxiety, disruptive behavior, and substance use). The ORs associated with types of CAs are always associated with increased odds (χ^2_{12}=44.5-193.7, $P<.001$). Those for MFF CAs are more consistently significant (χ^2_7=38.2-115.2, $P<.001$) than are those for other CAs (χ^2_5=7.4-57.5, $P=.19$ to $<.001$) (**Table 3**). The ORs associated with number of CAs are always associated with decreased odds, although they are largely confined to MFF CAs (χ^2_6=19.4-50.9, $P=<.001$ to .004).

Close inspection finds what seems to be meaningful variation in the ORs associated with some MFF CAs, such as parental criminality consistently having its lowest OR and parental substance abuse its highest OR predicting respondent substance use disorders. The more striking pattern, though, is that each MFF CA is significantly associated with each disorder class with rather consistent ORs. The ORs of other CAs are less consistent, with only 25% significant at $P<.05$. Again, there seems to be some meaningful variation, most notably family economic adversity and respondent physical illness associated with anxiety but not mood disorders, but these differences are not statistically significant.

DIFFERENTIAL ASSOCIATIONS BY LIFE COURSE STAGE AND NUMBER OF PREVIOUS DISORDERS

Disaggregation by life course stage (childhood: aged 4-12 years, adolescence: aged 13-19 years, early adulthood: aged 20-29 years, and middle-later adulthood: aged ≥30 years)

[a] A separate person-year file was created for each of the 20 disorders, and these 20 files were then stacked. The models were estimated in a discrete-time survival framework with person-year as the unit of analysis using this stacked data set, thereby forcing the slopes to be constant across the 20 disorders. Each model controlled for person-year, age category, sex, 19 dummy variables for the outcome disorder category (ie, for the 20 disorders in the stacked data set), and controls for the previous onset of comorbid conditions that began up to age 17 years. The 5692 respondents had 11 047 disorder onsets, ranging from a low of 101 onsets for bipolar I disorder to a high of 1573 onsets for major depressive disorder. A total of 4 700 780 noncase (ie, not involving 1 of the 11 047 onsets) person-years existed across all disorders in the stacked data set. A 10% stratified probability subsample of these person-years was used as controls, each with a weight of 10 to decrease computation time. No bias in the estimation of ORs is introduced by sampling on the outcome owing to the fact that the sampling fraction cancels out in the estimation of ORs.[37] Estimates of population-attributable risk proportions, though, are biased by subsampling. The weight of 10 (ie, 1 / 10% = 10) was added to correct for this bias. Data on the prevalence of individual CAs and the distribution of the number of CAs separately in person-years with and without onsets of the disorders are available on request. For person-years with an onset, these prevalence estimates range from a low of 9.0% (physical illness) to a high of 28.5% (family violence).

[b] Models were estimated with 1 CA at a time in addition to the controls noted in the previous footnote.

[c] The model was estimated with all 12 CAs in addition to the controls noted in the first footnote.

[d] The model was estimated with dummy predictors for the number of CAs without any information about types of CAs. The same controls used in earlier models were included as well.

[e] The model was estimated with dummy predictors for the number of CAs and information about types of CAs. The same controls used in earlier models were included as well.

[f] Significant at $P<.05$, 2-tailed.

shows that the significant ORs of some, but not all, CAs persist throughout the life course (**Table 4**). The ORs associated with other CAs decline with age, but these declines are generally not statistically significant. The exceptions are significant declines with age in ORs for parental death (χ^2_3=8.1, P=.04), physical abuse (χ^2_3=22.9, $P<.001$), sexual abuse (χ^2_3=40.3, $P<.001$), and physical illness (χ^2_3=13.7, P=.003). The persistence of the OR for other parental loss throughout the life course is striking compared with the OR for parental death being significant only in childhood. More highly disaggregated analyses showed that age-related declines involving sexual abuse were consistent across all disorder classes (although significant only for mood disorders), whereas declines associated with physical abuse, parental death, and physical illness varied by class of disorder. (Detailed results are available on request.)

We also examined differential associations of CAs with the first onset of *DSM-IV*/CIDI disorders as a function of the number of previous lifetime disorders. (Detailed results are available on request from the author.) We found that the ORs associated with most CAs become smaller as the number of previous disorders becomes larger. This means that CAs are more strongly associated with the onset of temporally primary vs secondary disorders. The sign pattern of the associations between types of CAs and onset of disorders remains largely positive (ie, ORs >1.0) when number of previous disorders is 0 (11 of 12 ORs >1.0, 9 of 12 significant at $P<.05$), 1 (7 of 12 ORs >1.0, 0 of 12 significant at $P<.05$), or 2 or more (7 of 12 ORs >1.0, 6 of 12 significant at $P<.05$), but the magnitude of ORs is considerably stronger when number of previous disorders is 0, with median (interquartile range) values of the ORs being higher when number of previous

Abbreviations: CA, childhood adversity; CI, confidence interval; CIDI, Composite International Diagnostic Interview; MFF, maladaptive family functioning; OR, odds ratio.

[a] See footnote "a" to Table 2 for a description of the data set and overall modeling approach. The model used herein was estimated with predictors for types of CAs and number of CAs (distinguishing number of MFF CAs from number of other CAs) in addition to the controls used in the models described in Table 2. Note that no term was included in the model for having exactly 1 CA. This means that the coefficients for types of CAs can be interpreted as the associations of pure CAs (ie, having 1 and only 1 particular type of CA compared with having none) with onset, whereas the associations with number of CAs represent the extent to which the incremental associations of co-occurring CAs (ie, the added risk of an additional CA in respondents who are otherwise equivalent in terms of the number of other CAs they experienced, controlling for types of other CAs) differ from the associations of pure CAs. The 5692 respondents had 11 047 disorder onsets, including 4545 onsets of an anxiety disorder, 2366 of a substance use disorder, 2357 of a mood disorder, and 1621 of a disruptive behavior disorder. Data on the prevalence of individual CAs and the distribution of the number of CAs separately in person-years with and without onsets of the disorders are available on request. For person-years with an onset, these prevalence estimates range from a low of 7.7% (physical illness associated with onset of a substance use disorder) to a high of 33.5% (family violence associated with onset of a disruptive behavior disorder).

[b] Disruptive behavior disorders are restricted to respondents 44 years and younger at interview.

[c] Significant at $P<.05$, 2-sided test.

disorders is 0 (1.6 [1.2-1.7]) rather than either 1 (1.2 [1.1-1.2]) or 2 or more (1.2 [1.1-1.3]).

POPULATION-LEVEL ASSOCIATIONS OF CAs WITH DISORDER ONSET

We calculated the PARPs associated with CAs based on the best-fitting model. Results show that CAs explain (in a predictive sense) 32.4% of all disorders, 41.2% of disruptive behavior disorders, 32.4% of anxiety disorders, 26.2% of mood disorders, and 21.0% of substance use disorders (**Table 5**). The CAs explain a higher proportion of childhood-onset disorders (44.6%) than adolescent-onset disorders (32.0%) and adult-onset disorders (28.6% and 25.9%). This decline is largely explained by the PARPs for mood disorders decreasing with age from a high of 57.1% for childhood-onset cases to a low of 20.5% for onsets in the age range of 30 years or older. The PARPs also decrease with age for anxiety disorders, but less dramatically than for mood disorders (from 39.5% of childhood-onset cases to 29.8% of onsets in the age range of ≥30 years). The PARPs do not decrease with age, in comparison, for substance use disorders. The number of disruptive behavior disorders that occur for the first time in adulthood is so small that we could not calculate the PARPs for these disorders beyond adolescence.

[a] See footnote "a" to Table 2 for a description of the data set and the overall modeling approach. The model used herein was estimated using predictors for types of CAs and number of CAs (distinguishing number of MFF CAs from number of other CAs) in addition to the controls used in the models described in Table 2. See footnote "a" in Table 3 for a description of the interpretation of the joint effects of type and number of CAs. The 5692 respondents had a total of 11 047 disorder onsets, including 3550 in the age range of 4 to 12 years, 3401 in the age range of 13 to 19 years, 2093 in the age range of 20 to 29 years, and 1845 in the age range of 30 years and older. Data on the prevalence of individual CAs and the distribution of the number of CAs separately in person-years with and without onsets of the disorders are available on request. For person-years with an onset, these prevalence estimates range from a low of 7.7% (physical illness associated with onsets in the age range of 20-29 years) to a high of 31.0% (family violence with onsets in the age range of 4-12 years).

[b] Significant at $P < .05$, 2-sided test.

EFFECTS OF TIME TO RECALL

The use of retrospective data introduces the possibility of recall bias. We investigated this possibility by examining age differences in the reported prevalence of CAs and in the ORs of CAs with disorder onset. (Detailed results are available on request from the author.) Reported death of a parent when the respondent was a child was positively related to age, whereas parental divorce when the respondent was a child was inversely related to age. These patterns are consistent with historical trends. Respondent age was unrelated, in comparison, to reports of other parental loss, neglect, or life-threatening childhood physical illness. Respondent age of 65 years and older was significantly related to low reports of parental mental illness, substance abuse, criminality, family violence, physical abuse, and sexual abuse, whereas age was generally unrelated to these CAs in the age range 18 to 64 years. These patterns could be due to a genuinely low prevalence of some CAs in older respondents, underrepresentation of elderly people with these CAs in the sample (due to early death or differential participation), or underreporting of these CAs in elderly respondents (due to differential recall or differential willingness to report). Although we have no way to know which of these processes are at work, any bias in prevalence estimates is likely conservative in the total sample because of lower reporting in the elderly respondents.

Analysis of age differences in associations at given life course stages found generally good consistency between ORs estimated in the youngest cohorts only (aged 18-29 years at interview) and in the entire sample. Of the

Table 5. Population-Attributable Risk Proportions (PARPs) of Lifetime *DSM-IV*/CIDI Disorder Types Associated With Childhood Adversities by Life Course Stage[a]

	PARPs				
	Overall	Childhood, Aged 4-12 y	Adolescence, Aged 13-19 y	Early Adulthood, Aged 20-29 y	Middle-Later Adulthood, Aged ≥30 y
Mood	26.2	57.1	30.5	24.7	20.5
Anxiety	32.4	39.5	28.7	31.3	29.8
Substance use	21.0	[b]	26.1	25.6	32.1
Disruptive behavior[c]	41.2	34.4	38.9	[b]	[b]
Any	32.4	44.6	32.0	28.6	25.9

Abbreviation: CIDI, Composite International Diagnostic Interview.

[a] The PARPs were calculated using simulation methods to generate individual-level predicted probabilities of the outcome disorders twice from the coefficients in the best-fitting model: the first time using all the coefficients in the model (probability of the disorder in those exposed to childhood adversities) and the second time assuming that the coefficients associated with the childhood adversities were all zero (probability of the disorder in those unexposed). One minus the ratio of the predicted prevalence estimates in the 2 specifications was then used to calculate PARP. In the pooled data set, the PARP value is the average PARP across all disorders included in the calculation based on a constant model across disorders.

[b] Too few cases available to estimate the PARP.

[c] Disruptive behavior disorders are restricted to respondents 44 years and younger at interview.

48 coefficients for individual CAs (12 CAs associated with disorder onsets in the person-year ranges of 4-12, 13-19, 20-29, and ≥30), 36 were positive and 21 were significant in the youngest cohorts, compared with 41 positive and 31 significant in the total sample. Median (interquartile range) ORs were also similar in the youngest cohorts (1.3 [1.1-1.5]) and the total sample (1.4 [1.2-1.7]). In 8 of 48 cases, the ORs differed significantly for the youngest vs the older cohorts. The OR was significant but was lower in magnitude in the younger (1.2-1.8) vs the older (1.4-1.4) cohorts in 3 of these cases. The OR changed from greater than 1.0 (1.1-1.1) in the older cohorts to less than 1.0 (0.7-0.9) in the younger cohorts in 2 other cases but was nonsignificant in both. The OR was nonsignificant in the youngest cohorts (0.8-1.1) but was significant in older cohorts (1.4-1.7) in the other 3 cases, which involved associations of childhood sexual abuse with disorder onsets in the age ranges of 20 to 29 years and 30 years and older and of parental substance abuse with disorder onsets in the age range of 30 years and older. These findings are not definitive because recall failure could exist even for respondents with the shortest recall intervals, but they nonetheless show that the results are stable across a range of recall times.

COMMENT

Despite these results, this study is limited by the retrospective nature of the data. Methodological research suggests that recall bias can lead to underreporting of CAs,[38] which would be expected to make the estimates of PARPs conservative. However, bias could be anticonservative in estimating ORs if the same respondents who did not report CAs also underreported disorders. A long-term prospective study is needed to resolve these uncertainties. Several such studies[39-42] exist that could be used to evaluate these results, but these studies generally have nontrivial attrition. If this attrition is systematic (ie, respondents with the highest risk of disorders also have the highest attrition), estimates of CA effects could be biased downward. The best way to guard against this possibility is to think of retrospective and prospective studies as bounding the true values of associations (ie, retrospective studies giving upper bound estimates and prospective studies lower bound estimates).

A second study limitation is that the list of CAs, although larger than that in most previous studies, is not exhaustive. We also did not consider the timing, sequencing, persistence, recurrence, or severity of individual CAs. In some cases, such as parental mental illness, there could be complex associations remaining to be discovered that involve the number of ill parents, the number of illnesses, and the persistence and severity of these illnesses. A related limitation is that the analysis of joint CA effects did not include fine-grained evaluation of interactions but focused only on broad interaction patterns. This broad-gauged approach is probably desirable as a first approximation but inevitably misses important subtleties. For example, some research[43-45] suggests that parental divorce is associated with a reduced risk of subsequent psychiatric disorders if it facilitates escape from exposure to maladaptive parenting. Future analyses need to examine such specifications against the backdrop of the broader preliminary patterns found in the present study.

In the context of these limitations, the present results are consistent with those of previous studies in suggesting that most US children are exposed to childhood family adversities that are often clustered.[7,9] Neglect, in particular, almost always appears with other CAs. Even the CAs most likely to be independent co-occur with at least one other CA in most cases. Because of this high co-occurrence, it is critical for future research not to focus on one CA without considering others, because bivariate analyses artificially inflate estimates of individual CA effects.[13] There are implications as well for more subtle analyses. For example, some previous research[11] suggested that childhood neglect exacerbates the predictive effects of other CAs, but the present results raise the possibility that this finding is due to neglect being associated with an especially large number of other un-

Downloaded From: http://archpsyc.jamanetwork.com/ by a University of Alabama-Birmingham User on 07/25/2015

controlled CAs rather than itself creating a high risk of psychiatric disorders.

The present finding that the multivariate structure of the associations between CAs and disorder onset is broadly subadditive has, to our knowledge, never before been examined. This subadditive pattern has important implications for intervention because it means that prevention or amelioration of only a single CA in youths exposed to many CAs is unlikely to have important preventive effects. The finding that this nonadditivity is confined to MFF CAs is reminiscent of the finding in the child maltreatment literature that the most severe CAs tend to be chronic intrafamilial adversities involving the use of physical force.[46] This finding also reinforces the importance of considering CA persistence and severity in future research because the finding that people exposed to many co-occurring MFF CAs have a very high risk of lifetime disorders might be due at least partly to the effects of unmeasured CA persistence and severity.

Despite considerable early theorizing to suggest unique effects of particular CAs on particular mental disorders, such as of childhood parental death on adult depression,[47] we found remarkably little specificity of this sort in the NCS-R data. Most CAs we studied, especially MFF CAs, were associated with all the disorder classes we considered. This pattern was found even in the models that controlled for number of CAs, in which ORs associated with specific CA types can be interpreted under the model as the associations of pure CAs (ie, having a particular 1 and only 1 CA vs none) with disorder onset, thereby removing the confounding effects of CA co-occurrences. We also controlled for comorbid child-adolescent disorders to increase the ability to detect specificities of this sort. Previous studies[48,49] found some evidence of specificity in predicting prevalent cases, but inspection of coefficients in the best-fitting models at the level of disorder class and the level of individual disorders (the latter results are available on request) yielded little evidence of specificity. The obvious implication is that the causal pathways that link CAs to the onset of psychiatric disorders are quite general.

In considering the theme of causal pathways, note that these results do not confirm that CAs have causal effects. An alternative possibility is that unmeasured third variables caused CAs and subsequent mental disorders. Genetic factors are possible confounding variables of this type. This is most obviously true for parental mental illness, which can predict respondent mental illness through genetic pathways unrelated to CAs, but the same might be true for other CAs to the extent that they are indicators of genetic liability. Gene × environment interactions could also be involved to the extent that the people exposed to CAs have an elevated genetic risk of psychiatric disorders and are exposed to stressful experiences related to their CAs that potentiate this genetic liability. Genetically informative designs (eg, twin-family and adoption studies) are needed to evaluate these possibilities rigorously.

Another class of potentially important third variables is respondent behaviors and behavioral predispositions that elicit some CAs, such as abuse, and cause the subsequent onset of respondent mental disorders. Prospective studies that measure these proposed constructs repeatedly would be in the best position to evaluate this possibility. In the ideal case, such studies would have multiple informants to assess reporting bias.

A final noteworthy finding is that the associations of many, but not all, CAs with first onset of *DSM-IV* disorders persist into adulthood. Future research needs to investigate the causal pathways responsible for this specification. Although previous research[15,50] has documented long-term associations of some CAs with adult disorders, these studies almost entirely focused on prevalent cases rather than on first onsets. It is much more striking to document, as we did herein, that CAs continue to be related to first onsets of *DSM-IV* disorders beyond early adulthood. Indeed, the PARPs calculated herein suggest that CAs are associated with more than one-fourth of all new disorders in adulthood. Although several hypotheses could be advanced to explain this finding,[50-52] nothing in these results sheds light on them. The indirect retrospective documentation of long-term multivariate associations is nonetheless important in providing an empirical justification for conducting further analyses to explore such hypotheses to investigate mediators, developmental sequences, and dynamic relationships between CAs and adult-onset disorders.

Future research also needs to distinguish between associations of CAs with disorder onset and disorder persistence. As reported in a companion article,[20] we found a rather different association of CAs with disorder persistence than reported herein with disorder onset. In addition, future research should integrate the kind of broad-based analyses of joint effects presented herein with more focused investigations of specific adversities[53,54] and important adversity clusters.[2,55] Future studies should also examine the moderating effects of early disorders on the associations of CAs with later disorders,[56] a line of study that could be important in focusing clinical attention on preventing the onset of secondary disorders. Finally, future studies should try to identify risk and protective factors in adulthood (eg, personality, social support, and adult stressors) that mediate or modify the relationships of CAs with adult disorders.

Closed-loop neuromodulation in an individual with treatment-resistant depression

Katherine W. Scangos[1,2] ✉, Ankit N. Khambhati[1,3], Patrick M. Daly[1,2], Ghassan S. Makhoul[1,2], Leo P. Sugrue[1,4], Hashem Zamanian[1,2], Tony X. Liu[1,2], Vikram R. Rao[1,5], Kristin K. Sellers[1,3], Heather E. Dawes[1,3], Philip A. Starr[1,3], Andrew D. Krystal[1,2,6] and Edward F. Chang[1,3,6]

Deep brain stimulation is a promising treatment for neuropsychiatric conditions such as major depression. It could be optimized by identifying neural biomarkers that trigger therapy selectively when symptom severity is elevated. We developed an approach that first used multi-day intracranial electrophysiology and focal electrical stimulation to identify a personalized symptom-specific biomarker and a treatment location where stimulation improved symptoms. We then implanted a chronic deep brain sensing and stimulation device and implemented a biomarker-driven closed-loop therapy in an individual with depression. Closed-loop therapy resulted in a rapid and sustained improvement in depression. Future work is required to determine if the results and approach of this *n*-of-1 study generalize to a broader population.

Major depressive disorder (MDD) is a common disorder with high rates of treatment resistance[1]. Deep brain stimulation (DBS) has shown promise as a treatment for refractory MDD but inter-individual response heterogeneity has contributed to inconsistent findings in definitive clinical trials[2–4]. Open-loop approaches deliver fixed, constant stimulation to a single brain structure and have been successful in Parkinson's disease and epilepsy. In MDD, however, evidence that different neural circuits underlie different subsets of MDD symptoms speaks for personalized circuit targeting[5].

There is also need for personalization via temporally controlling stimulation as in closed-loop neuromodulation, where a patient's own physiological activity is used to selectively trigger stimulation only when a pathological state is detected[6]. Because the mood-related effects of neuromodulation exhibit state dependence[7], this temporal specificity may be critical for success in patients with MDD with frequent state changes. Closed-loop stimulation also mitigates concerns for neural adaptation, preserves battery life and reduces side effects. However, closed-loop therapy requires a symptom-specific biomarker that has not previously been identified in MDD. In this study, we report our experience with a patient, where we identified a biomarker of MDD symptoms during a 10-d period of intracranial corticolimbic circuitry mapping. We then successfully implemented the biomarker in implanted closed-loop therapy. This is a demonstration of chronic closed-loop neuromodulation in a psychiatric disorder.

The patient was a 36-year-old woman with childhood onset severe and treatment-resistant MDD (Montgomery–Åsberg Depression Rating Scale (MADRS) = 36 out of 54) unresponsive to multiple antidepressant combinations and electroconvulsive therapy, who participated in a personalized closed-loop neurostimulation trial[7]. We first performed stimulus-response mapping of emotion circuitry employing ten stereoelectroencephalography (SEEG) electrodes implanted bilaterally in the orbitofrontal cortex (OFC), amygdala, hippocampus, ventral capsule/ventral striatum (VC/VS) and subgenual cingulate cortex (SGC). We found dimensionally restrictive clinical responses to stimulation across corticolimbic circuitry aligning with different types of depression symptoms[7]. Neural activity was recorded continuously for 10 d while the patient completed symptom rating scales used to define high and low symptom severity states (Fig. 1a,b).

We then identified SEEG spectral activity features in 6 standard frequency bands that discriminated 15-min segments of resting-state activity coinciding with high and low symptom states ($n = 35$) employing two cross-validated supervised machine learning models at different spatial resolutions. We found that bilateral amygdala gamma power alone was sufficient to detect the high symptom severity state (accuracy: mean = 0.77, s.d. = 0.09; area under the curve (AUC): mean = 0.82, s.d. = 0.11; Fig. 1c and Extended Data Fig. 1a).

We identified right VC/VS as the stimulation site that led to consistent, sustained and dose-dependent improvement of symptoms[7]. We next examined connectivity to determine whether right hemispheric VC/VS and amygdala nodes constituted a structurally and functionally connected subnetwork. We performed evoked potential mapping to generate a global directed network graph[8] (Fig. 1d) and quantified node-relative importance. We found that the amygdala and hippocampus integrated signals from many brain regions (highest weighted indegree) while VC/VS influenced many distant brain regions (highest weighted outdegree; Fig. 1e). Furthermore, the VC/VS-stimulated evoked response was stronger in the amygdala (Fig. 1f) than other network nodes (Extended Data Fig. 1b). Using deterministic tractography we next identified axonal fiber tracts underlying this effective connectivity. Dense right VC/VS-amygdala structural connectivity consisted of the stria terminalis and ansa peduncularis (Fig. 1g and Extended Data Fig. 1c). Finally, VC/VS stimulation at contacts $2^+/3^-$ improved clinical symptoms on 11 out of 13 trials. We examined the change in amygdala gamma power with stimulation with a variety of stimulation paradigms and baseline symptom severities where we had clinical and SEEG data ($n = 5$ trials). We observed a reduction in amygdala gamma power on both trials where symptom severity improved, which was absent on trials when symptom severity did not improve due to alternate

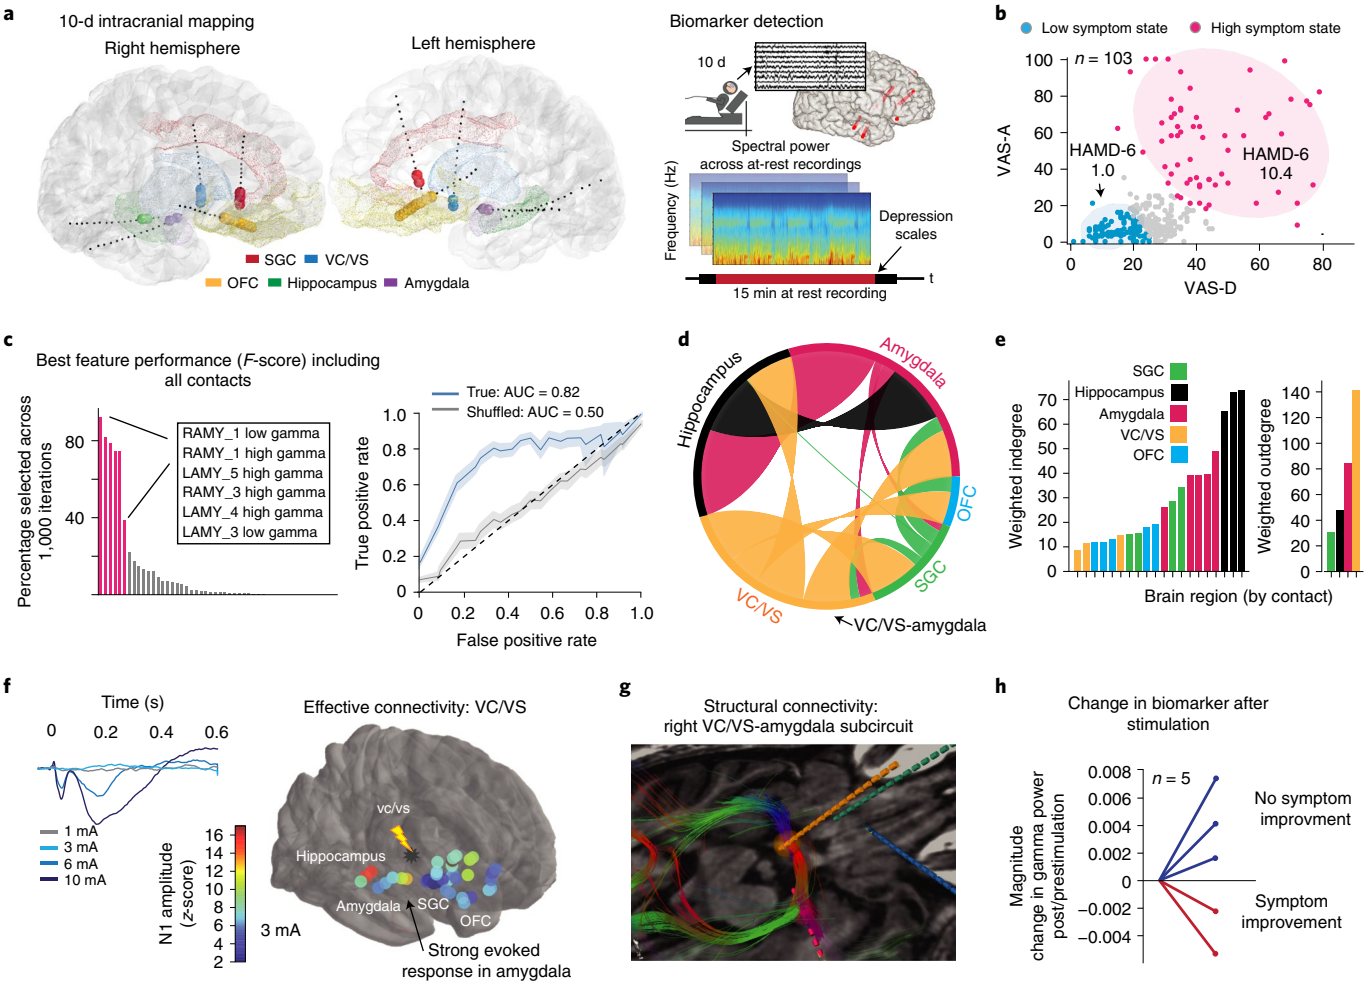

Fig. 1 | Neural biomarker and limbic subnetwork of depression. a, Location of intracranial electrodes and overall approach for biomarker detection. **b**, Clustering clinical reports on anxiety and depression dimensions resulted in two symptom states. Shading has been added to aid visualization. **c**, Top neural features (defined by *F*-score, ANOVA) that discriminated high versus low symptom severity states. Receiver operating characteristic curves reflect the mean ± s.e.m. over $n = 1{,}000$ randomly sampled features for the true (blue) and shuffled models (gray). **d**, Directed network graph of right hemisphere where percentage circumference indicates the strength of connection between any two brain regions. The color indicates the starting location for each set of connections. **e**, Connectivity strength from the network graph was quantified by calculating the weighted indegree and outdegree. The values represent the sum of incoming/outgoing evoked potential waveform N1 (10–50 ms poststimulation) amplitudes, averaged over $n = 20$ repeated pulses. **f**, Example of dose-dependent mean-evoked potentials (left). Summary of evoked potentials across the corticolimbic network due to single pulses in the right VC/VS is shown overlayed on the brain as a heatmap (right). Warmer colors indicate a larger N1 amplitude. **g**, Location of right-sided iEEG leads with fiber tracts (color-coded by orientation) showing structural connections between the amygdala and clinically responsive VC/VS electrodes. Lead location is indicated by color as in **d**,**e**. **h**, Change in gamma biomarker after a period of continuous stimulation for those trials that led to a reduction in symptom severity (red) and those that did not reduce symptom severity (blue).

stimulation paradigms, minimal baseline symptoms or a primary effect on activation over depression (Fig. 1h).

We next implanted the U.S. Food and Drug Administration (FDA)-approved NeuroPace RNS System[9] unilaterally in the right hemisphere (Fig. 2a), with two separate sensing/stimulation four-contact depth leads placed in the amygdala and VC/VS, respectively (Fig. 2b). The NeuroPace RNS System continuously senses neural activity; detection of prespecified patterns of activity are coupled to delivery of electrical stimulation to designated electrodes. Using the NeuroPace RNS System telemetry wand, we wirelessly streamed 10-min trials of continuous amygdala real-time electrocorticography while the patient engaged in naturalistic activities (for example, social media, virtual therapy). We then paired the neural activity with clinical severity ratings (Fig. 2c) and found that the symptom-specific amygdala gamma power replicated findings from the 10-d intracranial mapping. It was highly correlated with both the visual analog scale-depression (VAS-D) ($r^2 = 0.79$, $P = 4.6 \times 10^{-5}$), VAS-anxiety (VAS-A) ($r^2 = 0.53$, $P = 7.5 \times 10^{-3}$) and the 6-item Hamilton Depression Rating Scale (HAMD-6) ($r^2 = 0.68$, $P = 6.5 \times 10^{-4}$; Fig. 2d) and significantly differentiated the high and low symptom severity states (analysis of variance (ANOVA), $F = 6.37$, $P = 0.012$).

The clinical effect of right VC/VS stimulation also replicated results from the intracranial mapping study. Bipolar stimulation at the VC/VS contacts that engaged the stria terminalis and ansa peduncularis (contacts $2^+/3^-$, $3^+/4^-$, 100 Hz, 120 µs, 1–2 mA) led to acute dose-dependent symptom improvement across most trials and the effect was strongest and preferred by the patient (pleasurable/energizing) at the predicted location (contacts $3^+/4^-$) compared to other VC/VS and amygdala contact pairs (Fig. 2e). Furthermore,

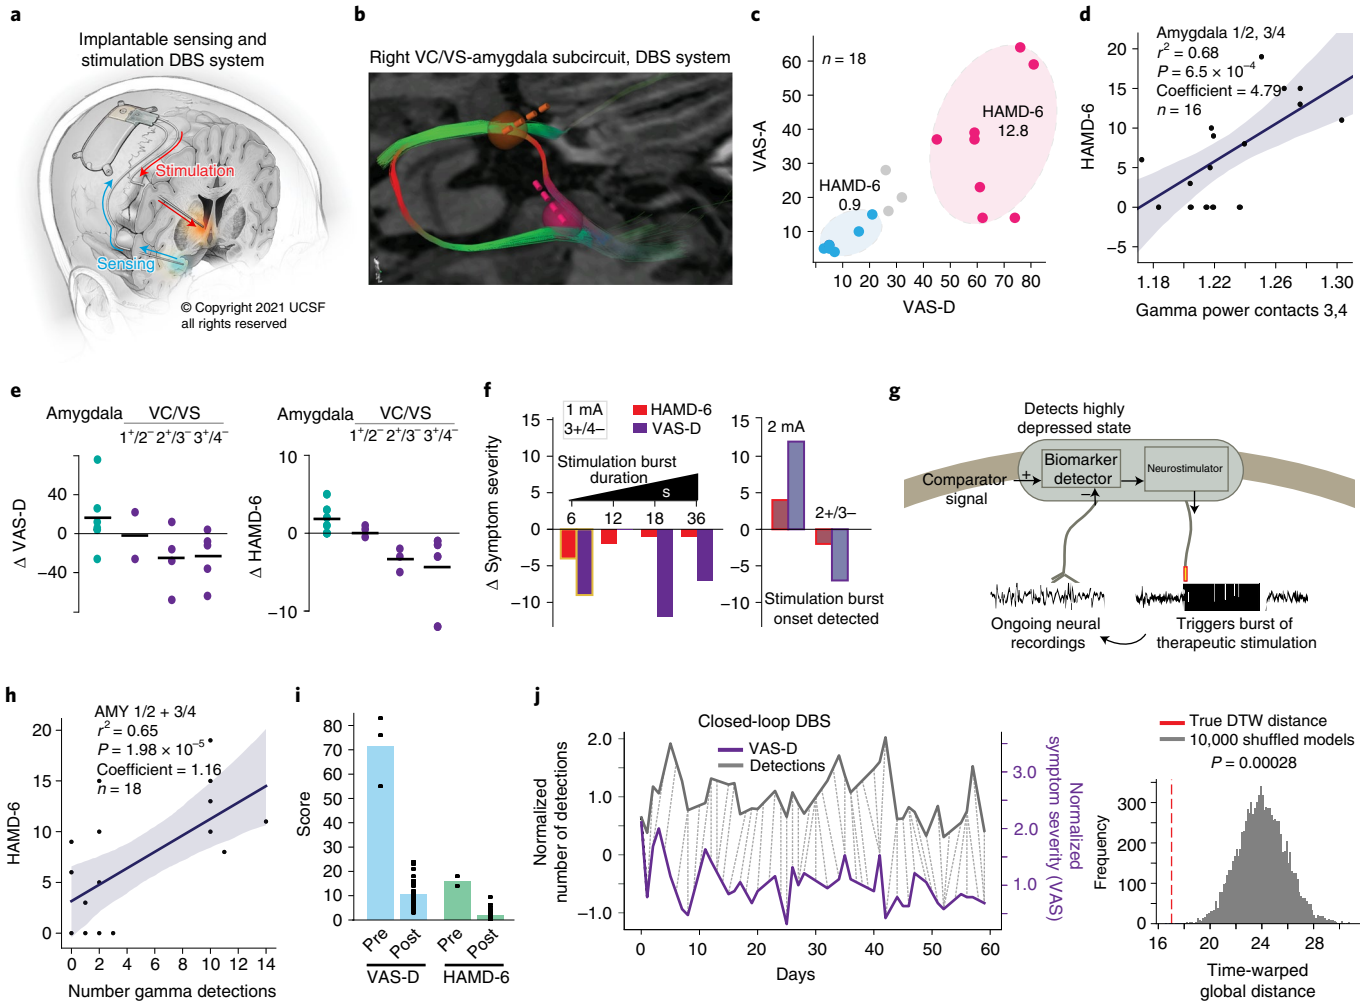

Fig. 2 | Implementation of closed-loop neuromodulation. a, Fully implantable DBS system (illustrated by K. X. Probst). **b**, Reproducibility of targeting showing robust engagement of the stria terminalis and ansa peduncularis. VC/VS lead, yellow; amygdala lead, pink. **c**, Distribution of symptom severity scores in relation to clusters identified in the mapping study. **d**, Positive correlation between gamma power in amygdala contacts 1/2 and 3/4 within the 10-min trials and HAMD-6 score. The linear regression model was evaluated using a two-sided *F*-test and *P* values were adjusted for multiple comparisons. The linear model fit is presented as the mean ± s.e.m. over $n = 16$ symptom ratings. **e**, Reproducibility of clinical effects. Each point represents a stimulation trial ($n = 6, 2, 4, 5$ for VAS-D; $n = 6, 2, 3, 4$ for HAMD) at different bipolar configurations across the right VC/VS and amygdala. **f**, Left: Effect of burst duration on clinical measures. Stimulation parameters: contact $3^+/4^-$, 1 mA, 36 s total stimulation across 15.6 min in 6–36 s intervals. Highlighted condition (6-s burst duration) selected for implementation of closed-loop therapy. Right: Effect of increasing dose (1–2 mA) and changing contacts ($3^+/4^-$ to $2^+/3^-$) on clinical measures. The faded colors indicate that ON/OFF states were detected by the patient (one trial per condition). **g**, Schematic of closed-loop control. **h**, Positive correlation between number of gamma detections by the NeuroPace RNS System within 10-min trials as in **d** and HAMD-6 score. The linear regression model was evaluated using a two-sided *F*-test and *P* values were adjusted for multiple comparisons. The linear model fit is presented as the mean ± s.e.m. over $n = 18$ gamma detections. **i**, Symptom severity scores in the week pre- versus postclosed-loop stimulation onset ($n = 3, 31$ for VAS-D, $n = 2, 30$ for HAMD-6). **j**, Relationship between daily mood ratings (purple) and number of daily biomarker detections (gray). The dotted lines indicate the DTW-computed distance between VAS-D scores and daily biomarker detection numbers (left). Significance was assessed by comparing the DTW distance to that computed from 10,000 randomly scrambled biomarker time series (right).

6 s of intermittent stimulation at 1 mA was clinically effective and below the patient's perceptual threshold (Fig. 2f). Increasing the dose to 2 mA or changing contacts led the patient to perceive stimulation and worsened the clinical response on some trials.

We then implemented closed-loop therapy such that 6 s of stimulation were delivered following the device's automated biomarker detection (Fig. 2g). We found that the number of detections, defined as gamma power crossing a threshold of 0.8% of full amplitude scale within 10-min recording periods was 87% predictive of symptom severity state and highly correlated with VAS-D ($r^2 = 0.59$, $P = 1.2 \times 10^{-4}$), VAS-A ($r^2 = 0.52$, $P = 4.6 \times ^{-4}$) and HAMD-6 ($r^2 = 0.65$, $P = 1.98 \times 10^{-5}$; Fig. 2h). Over the course of 2 months, we found that on average, there were 468 detections distributed across the daytime (s.d. = 206) with minimal nighttime stimulations. We set a stimulation cap of 300 therapies per day (30 min total stimulation) so as not to disturb sleep from evening therapy.

Implementation of closed-loop therapy rapidly improved both symptom severity (measured daily with the HAMD-6/VAS scales) and depression (periodic MADRS). The individual's MADRS score dropped from a 33 before turning treatment ON to a 14 at the first during-treatment assessment carried out after 12 d of stimulation and dropped below 10 (remission) several months later. Similarly, her HAMD-6 and VAS-D scores dropped precipitously the morning after stimulation started (HAMD-6 = 12.0 to 1.0; VAS-D = 77

to 23) and were lower the week after stimulation was turned ON versus the previous week (HAMD-6 = mean 16 (s.d. = 2.82) to 1.6 (s.d. = 1.60), Welch's *t*-test $P = 0.08$; VAS-D = 77.33 (14.57) to 10.48 (5.74), Welch's *t*-test, $P = 0.02$; Fig. 2i).

To evaluate whether our algorithm triggered stimulus delivery linked to patient symptoms, and not randomly, we used dynamic time warping (DTW) to nonlinearly align daily symptom severity (VAS-D) and biomarker detection count time traces over two months and calculated their relative postalignment distance[10]. We found that fluctuation in daily symptoms was significantly associated with the fluctuation in number of device-detected biomarker events ($P = 2.8 \times 10^{-4}$; Fig. 2j). This suggests that our biomarker detection algorithm detects changes in symptom severity significantly better than random chance.

In conclusion, we show the successful development of a personalized biomarker of depression-specific symptoms and implementation of closed-loop therapy for MDD. Success was predicated on a clinical mapping stage before chronic device placement, a strategy that has been utilized in epilepsy to map seizure foci in a personalized manner but has not previously been performed in other neuropsychiatric conditions. During this stage, we developed a comprehensive multimodal framework for selection of sensing and stimulation brain targets (Extended Data Fig. 2). Our approach included personalized stimulus-response mapping, pairing of resting-state signals with clinical symptom measures and identification of functionally and structurally connected subnetworks across the corticolimbic network.

Network mapping and biomarker discovery suggested that VC/VS-amygdala represented an important limbic subnetwork in this patient. Amygdala gamma power reflected depression severity and could be modulated by VC/VS stimulation to decrease clinical symptoms. Previous work showed that these brain regions are important nodes within the mood regulatory circuitry[11]. Bursts of high-frequency amygdala activity correlate with emotion states in humans[12] and VC/VS has been a thoroughly studied DBS target for depression[13] and may be particularly effective for treating anhedonia given its role in the reward pathway. Thus, successful reduction in amygdala gamma may be a requirement for symptom improvement. We validated the amygdala gamma biomarker using the NeuroPace RNS System and identified a set of detection algorithms that enabled us to successfully translate this marker into closed-loop treatment. While traditional DBS is performed bilaterally, we performed right-sided unilateral therapy based on the clinical mapping study and safety considerations. Reasons for observed hemispheric differences are unknown but could be lateralization of emotion regulation or electrode placement within the VC/VS bilaterally.

Our single-participant study cannot evaluate whether the VC/VS-amygdala subcircuit or amygdala biomarker is present in all individuals. Previous literature suggested that the SGC is another promising site for closed-loop stimulation in some individuals[14]. Our methodology intentionally accounts for intersubject variability in MDD symptoms. In contrast to previous DBS studies, a randomized controlled trial using this approach would identify a unique biomarker and treatment site for each individual. It is possible that this personalized approach will overcome limitations evident in previous randomized controlled trials where efficacy was not found when stimulating the VC/VS (or SGC) in all participants[2–4]. In the future, group-level analyses may assess whether certain symptom profiles are predictive of a stimulation target and help define symptom state thresholds that enhance biomarker identification.

We conceptualized MDD as a dynamic process where symptoms arise when a dysfunctional activity state emerges in one or more prefrontal/limbic brain networks subserving mood-related functions. In this model, stimulation has an immediate impact on symptom severity. An acute response to VC/VS stimulation was observed in previous studies in intraoperative or programming periods[15]. Yet, is not always sustained once continuous stimulation is initiated. By delivering intermittent stimulation in a closed-loop manner, we hypothesize that we can repeatedly obtain these acute effects and employ them to treat depression. In line with our model, this patient's depression acutely improved once closed-loop therapy was initiated and the effect has been maintained with sustained closed-loop therapy through the time of writing this article. Both the rapidity and intensity of this clinical response was highly unusual in treatment-resistant depression, where the 1-year remission rate for 'treatment as usual' is approximately 3.5%[16] and symptom relief from DBS can take months to emerge[2].

There are several limitations to this study. First, is the *n*-of-1 sample. It is unknown if the results will generalize. Furthermore, while the patient was blinded to stimulation location and parameters, the clinicians were usually but not always blinded. It is possible that this affected therapeutic response. It is also possible that non-affective sensations elicited during stimulation influenced her affective response. We made efforts to minimize this likelihood by keeping the patient blinded and reducing stimulation intensity if such sensations were observed or reported. Due to device capabilities, we were limited to exploring biomarkers in the power domain in a few frequency bands that could be detected in a time window of a few seconds. New device capabilities that sense continuous neural activity and have the capability to integrate information on the timescale of minutes may improve our ability to incorporate more complex biomarkers into closed-loop control[17]. The degree of network plasticity or drift in the biomarker signal across time is another area for future work. The intent of this study was not to address the efficacy of closed-loop neuromodulation for MDD, which would require a double-blind, randomized controlled, adequately powered study. In this study, we established proof-of-concept for a new powerful treatment approach for neuropsychiatric disorders. The new framework presented in this article could advance biomarker-based neural interfaces and enhance the mechanistic understanding and treatment of a broad range of neuropsychiatric conditions.

Methods

Participant. In this *n*-of-1 study, the patient was a 36-year-old woman with childhood onset severe, treatment-resistant MDD (MADRS = 36 out of 54) unresponsive to multiple antidepressant combinations and electroconvulsive therapy.

Surgical procedure. The patient gave written informed consent for participation in a clinical trial of closed-loop neuromodulation for treatment-resistant MDD (PReSiDio: NCT04004169), approved by the institutional review board of the University of California, San Francisco (UCSF) and by the FDA. (Please see the Life Sciences Reporting Summary published along with this case report for additional details.) The patient underwent two implant surgeries. In the first, we surgically implanted ten SEEG electrodes (PMT Corporation) within the OFC, amygdala, hippocampus, VC/VS and SGC as described in Scangos et al.[7]. Exploratory intracranial stimulation and recording took place over a 10-d period (October 2019). After 10 d, the electrodes were explanted. In the second implant surgery, we implanted the NeuroPace RNS System with 2 four-contact-depth leads (30-cm lead length, 3.5-mm electrode spacing) in the right VC/VS and amygdala, guided by our findings in the 10-d recording and monitoring (mapping) period. Surgical targeting was planned using the Brainlab iPlan Cranial Software (v3.0) using diffusion tensor imaging (DTI)[18] or coordinate-based targeting[3] in accordance with published work. Computerized tomography was used intraoperatively to confirm electrode placement. No complications of surgery occurred.

Clinical measures. To assess moment-to-moment changes in MDD symptom severity, we used VAS-D[19] and VAS-A and the HAMD-6 of the HAMD-17, which is thought to capture the core symptoms of the full scale and has been used to assess the rapid effects of antidepressants[20–22]. Our symptom assessment strategy included an a priori plan to consider the dimensions of depression that can change in the course of a day as represented in the HAMD-6 subscale of the HAMD-17, which includes: (Q1) sadness; (Q2) guilt; (Q3) apathy; (Q4) fatigue; (Q5) anxiety; and (Q6) energy but focusing only on the dimensions that were possible to meaningfully operationalize in the setting of repeated testing with a VAS (depression, anxiety) and were the smallest number needed to reflect the symptom profile of the patient. Study data were collected and managed using the Research Electronic Data Capture (REDCap, v10.6.19) electronic data capture tools hosted at UCSF[23,24]. REDCap is a secure, Web-based software platform designed to support data capture for research studies, providing (1) an intuitive interface for validated data capture, (2) audit trails for tracking data manipulation and export procedures, (3) automated export procedures for seamless data downloads to common statistical packages and (4) procedures for data integration and interoperability with external sources. The patient performed her in-lab and at-home surveys using this tool on a study iPad. In the clinical mapping stage, she performed 335 VAS-D, VAS-A and HAMD-6 scales over the 10 d. Scores were distributed across the full range of the patient's natural emotions (VAS-A, mean = 17.5, s.d. = 21.7; VAS-D, mean = 26.3, s.d. = 12.9). These measures were used to define two symptom states (high and low symptom severity). Once the NeuroPace RNS System device was in place, the patient was asked to perform at-home surveys 2–3 times per day.

Signal processing. Intracranial electroencephalogram (iEEG) recordings derived from SEEG electrodes were used to derive measures of activity and connectivity. This is a high-resolution intracranial recording technique[25] and is commonly used in the presurgical evaluation of drug-resistant epilepsy. Stimulation through these electrodes (single pulses[26] or continuous stimulation[27]) was used to perform stimulus-response mapping, assess connectivity and assess the effects of perturbation to MDD networks. Data acquisition of iEEG recordings and evoked potential mapping were performed with a 256-channel Nihon Kohden clinical system and secondary data stream at a sampling rate of 10 kHz. Standard SEEG preprocessing techniques were conducted in Python and involved application of a 2–250 Hz bandpass filter, notch filters at line noise frequency and harmonics, downsampling to 512 Hz and common average referencing across all channels. Signal processing was performed using the continuous wavelet transformation (Morlet, 6-cycles)[28] at 30-s intervals to obtain power in 6 spectral frequency bands (delta = 1–4 Hz, theta = 5–8 Hz, alpha = 9–12 Hz, beta = 13–30 Hz, low gamma = 31–70 Hz, high gamma = 71–150 Hz). Artifacts in evoked potential analysis were removed with an eighth-order Butterworth filter.

Electrode stimulation. Our approach to clinical mapping is discussed elsewhere[7]. Briefly, we tested the clinical effect of a set of stimulation parameters used in the evaluation of patients with epilepsy (1 or 100 Hz, 100 µs, 1–6 mA) through a systematic bipolar stimulation survey and then blinded sham-controlled stimulation studies across 10 d. Where indicated, the brain stimulation configuration is represented by contact number and polarity (for example, $2^{+}/3^{-}$ reflects that contact 2 is anode and contact 3 is cathode). Once the NeuroPace RNS System device was in place, we repeated the bipolar stimulation survey and sham-controlled stimulation using the same clinical scales as outcome measures. The study was single-blinded such that the patient was blinded to stimulation location and parameters. Closed-loop neuromodulation introduces a new stimulation parameter—the burst duration delivered once a depressed state is detected. We tested the effect of burst duration in a systematic manner by delivering increasing durations of stimulation (6, 12, 18, 36 s bursts,100 Hz, 120 µs, 1 mA) while keeping total stimulation time constant over 15- and 30-min time intervals. Our strategy was to identify a set of parameters where intermittent stimulation was clinically effective over a time interval but each burst onset was not detected by the patient to prevent interfering with normal activities and select shorter more frequent bursts over less frequent but longer stimulation periods to increase specificity.

Biomarker discovery. The development of symptom-specific biomarkers in depression have been challenged by the lack of objectively observable clinical symptoms, such as those that exist in movement disorders, and the multidimensional nature of MDD. We addressed this challenge during the mapping trial in several ways. We included a high trial count to address inherent noise in the self-assessment of internal state. We also ensured there was variability across time in the measures by including the presence of mood variability as one of the inclusion criteria of the clinical trial and having the patient perform naturalistic activities in the laboratory setting that induced symptom state variation (for example, recalling life events, watching movies, using social media) during the 10-d period. Then, based on the anxiety and depression dimensions of the VAS scale, we sought to identify states of high and low symptom severity objectively using semisupervised *k*-means clustering. Specifically, to discriminate noisy ratings from clinically relevant ratings, we used cluster tuning and cluster aggregation to discriminate two symptom severity states based on the VAS ratings that best corresponded to the clinically established HAMD-6 scores.

To identify spectral biomarkers related to symptom severity state, we asked the patient to rest for 15-min and then assessed MDD symptom severity (self-reported HAMD-6, VAS scales) about 5 times each day. These 15-min intervals were required to be at least 1 h from stimulation to minimize any potential influence of stimulation on neural activity. Spectral power was calculated in 30-s intervals and averaged across the 15-min recording period to obtain power in 6 frequency bands. We then modeled differences in spectral power across symptom states to identify the spectral power features that were predictive of high symptom severity using cross-validated machine learning models. In the first model, the feature set was defined by spectral power averaged across all contacts within brain regions (10 regions × 6 bands = 60 features). In a second model, the feature set was defined by spectral power for each electrode contact (41 anatomically verified contacts × 6 bands = 246 features). The modeling pipeline consisted of feature selection based on ANOVA *F* value and classification using penalized logistic regression trained on 80% of the data and tested on the remaining 20%. We repeated the training/test schema 1,000 times to ensure stability in AUC score and feature importance histograms. Significance was assessed by comparing the output of our logistic classifier to a null model obtained from randomly permuting class labels 1,000 times.

In closed-loop mode, delivery of therapeutic stimulation is expected to normalize the biomarker that triggers the stimulation. To test the effect of VC/VS stimulation on biomarker activity, we examined the change in gamma power in two 30-s intervals before and after a period of continuous stimulation. We included all types of stimulation trials where we had sufficient iEEG activity and VAS scales. All stimulation was at 100 Hz, 100 µs and 1–3 mA, bipolar contacts $2^{+}3^{-}$. Stimulation was delivered continuously on 4 out of 5 trials. The change was examined in relation to the change in symptom severity due to stimulation.

We validated the biomarker once the NeuroPace RNS System was in place. In the laboratory setting, we streamed continuous neural data (electrocorticography) using the NeuroPace RNS System wand held over the cranially implanted neurostimulator with a flexible metal arm. Once the final RNS detection parameters were identified, we collected 18 trials with 10 min of resting-state neural activity followed by depression measures over the course of 7 d. As in the 10-d mapping period, the patient engaged in a range of naturalistic activities during the recordings. Logistic and linear regression models were then constructed to assess the relationship of amygdala gamma power and symptom severity state or VAS-D and HAMD-6 scores, respectively.

Effective connectivity. Effective connectivity is a functional connectivity measure that describes the directional influence of one brain region on another[29]. Intracranial EEG and intracortical stimulation offer the rare and unique capability to directly probe effective network connectivity through the delivery of brief stimulation pulses across adjacent contacts in one brain region and examination of the electrical effect of perturbation—the evoked potentials—in distant contacts. Evoked potential mapping was performed on day 1. We delivered bipolar single pulse stimulation (1, 3, 6 mA) at 0.5 Hz for 40 s to adjacent contact pairs across a central contact pair in each brain region. Standard methods were used[26] to measure and quantify evoked potentials including calculating the mean across 20 trials, *z*-scoring voltage against 50 ms of prestimulus baseline, identifying N1 and N2 by their peak deflection magnitude within the 10–50 and 50–500 ms time windows, respectively, constructing connectivity matrices from N1 response amplitude for the full set of evoked potentials and filtering on statistically significant evoked potentials to generate a directed network graph. We determined which electrodes exhibited statistically significant evoked potentials by comparing the distribution

of N1 responses due to 20 single pulses to the distribution of prestimulation baseline fluctuations. The baseline score quantified the amount of spontaneous voltage fluctuation in the absence of stimulation and was calculated by finding the peak deflection magnitude during the 50 ms before stimulation, *z*-scored against the mean voltage in the 50–100 ms window before stimulation. We used a one-sided Wilcoxon signed-rank test with Benjamini–Hochberg false discovery rate correction to determine if the N1 response was statistically larger than the baseline spontaneous fluctuation. Compared to a uniform *z*-score threshold, this approach allowed us to account for variable noise between electrodes and identify true evoked potentials with greater sensitivity.

In graph theory, a graph represents the electrophysiology network where nodes are considered to be individual electrodes and the directed link or edge between nodes represents the effect of stimulation of the source node on the amplitude of the neural signal at a distal node[30]. We computed two graph theoretical metrics from the evoked potential connectivity map—indegree and outdegree—to determine the direction and strength of functional connections between nodes and inform the relationship of stimulation and sensing target candidates. A node with high outdegree is a hub of high network influence in that stimulation there highly affects other nodes in the network and could be indicative of a good treatment target[31]. A node with high indegree suggests a region that is influenced by stimulation in other regions and may play a role in sensing modifiable neural signatures of MDD that normalize with stimulation elsewhere in the network. We calculated indegree by taking the weighted sum of significant connections (N1 amplitudes) pointed toward each node and outdegree by the weighted sum of significant connections projecting away from each node for right and left hemispheres and the total brain network. We identified those hubs that had the highest values and were directionally connected.

DTI. DTI can be used to map structural connectivity by identifying putative axonal fiber tracts that might mediate effective connectivity, thereby constraining our model of functional integration across distant brain regions[29]. Engagement of specific white matter tracts or the intersection of several tracts has been shown to improve outcomes in DBS for depression[32,33]. While the exact relationship between structural and functional connectivity is unknown, it has been suggested that structural connectivity properties can be implemented as an informative prior in a Bayesian model of effective connectivity[34]. Diffusion data were acquired using axial DTI high angular resolution diffusion imaging at 3 Tesla with a 32-channel head coil (B value = 2,000 s mm^{-2}, 55 directions). Tractography was performed using deterministic fiber assignment by continuous tracking[35], implemented within the Brainlab Fibertracking (v3.0) software. Tractography was based on 3-mm diameter spherical regions of interest centered on each contact of a candidate stimulation and sensing pair; DTI parameters were the same for all pairs with minimum fractional anisotropy = 0.1, minimum fiber length = 80 mm and maximum angulation = 20 degrees. The resulting fiber tracts are color-coded by orientation (red, left to right; green, anterior-posterior and blue, superior-inferior). Using these parameters, the number of streamlines was used to compare the strength of connectivity for each candidate stimulation-sensing pair (VC/VS stimulation-amygdala sensing, VC/VS stimulation-OFC sensing, SGC stimulation-amygdala sensing and OFC stimulation-amygdala sensing).

Closed-loop control. The NeuroPace RNS System was first placed in a sensing-only configuration where neural biomarkers could be detected but no stimulation was delivered (0 mA). For the first 2.5 months, we found a detection algorithm that could identify the amygdala gamma biomarker, modifying several parameters including detector number, bandpass threshold, window size and count criterion. Our final detector included the following parameters: pattern A1 (amygdala 3/4): minimum-maximum frequency = 28.8–125 Hz, minimum amplitude = 0.8%, window size = 160 ms, count criterion = 10, bandpass threshold = 3, detection analysis window size = 2,048; pattern A2 (amygdala 1/2): minimum-maximum frequency = 28.8–125 Hz, minimum amplitude = 0.8%, window size = 160 ms, count criterion = 10, bandpass threshold = 10, detection analysis window size = 2,048. This means a 'detection' was triggered when gamma power crossed a threshold of 0.8% of full amplitude scale assessed within a 2-s sliding window for amygdala contacts 3/4 or 1/2. While the NeuroPace RNS System does not implement standard frequency decomposition algorithms, the half-wave detector approximates frequency content. In combination with the minimal amplitude settings, the detector tracked gamma activity.

With this detector ON, we examined the number of detections in the 10-min resting-state intervals for the 18 trials utilized for biomarker validation. Logistic and linear regression models were constructed using the number of stimulations as the dependent variable and the symptom state or HAMD-6/VAS-D score as the independent variable. On day 74, the NeuroPace RNS System was turned on in closed-loop mode with stimulation ON (1 mA, 120 µs, 100 Hz). We capped therapy number at 300 per day (30-min total stimulation per day), which was reached at 81.1% of days. On days when the limit was reached, this occurred on average at 19:40 (s.d. = 3.3 h). This limit was selected because stimulation delivered into the evening hours interfered with the patient's sleep. Therapy limit reset time was at 7:00.

To investigate the relationship between daily symptom severity scores (VAS-D) and the time series of the daily number of biomarker detection counts, we used DTW, a method demonstrated to be effective at relating time series exhibiting naturalistic noise[36]. After normalizing symptom severity (VAS-D) and biomarker detection count time traces by their means, we computed the DTW warping function and distance[10]. To prevent the warping function from skipping important symptom severity or biomarker features and cohere with standard practice, we incorporated a Sakoe–Chiba warping window of size three[37]. We tested the significance of the symptom severity and biomarker relationship by comparing our DTW distance to DTW distances computed between symptom severity time series and scrambled biomarker detection time series, where the biomarker time series was obtained by randomly shuffling the observed values 10,000 times.

Reporting Summary. Further information on research design is available in the Nature Research Reporting Summary linked to this article.

Data availability

The data that support the findings in this article are available within the article itself, the source data and within our publicly available GitHub repository. Extended Data Fig. 1 | Network Activity and Connectivity. a. Biomarker identification was performed at two levels of spatial resolution (see also Fig. 1c). In the brain region level model, spectral power was averaged across all contacts within brain regions (60 features). Top neural features (defined by F-score, ANOVA) that discriminated high vs. low symptom severity states are shown. Gamma power in the bilateral AMY, right OFC, left SGC, and right HPC had high state discriminative potential (Accuracy: mean 0.73, std 0.08; AUC: mean 0.76, std 0.10). ROC curves reflect mean ± SEM over n=1000 randomly sampled features for the true model (blue) and the shuffled model (gray). **b**. Evoked potentials (z-scored relative to baseline) across the corticolimbic network due to single pulse stimulation in the right VC/VS, OFC and SGC is shown overlayed on brain as heatmap. Warmer colors indicate a larger N1 amplitude. **c**. Location of right sided sEEG leads targeting AMY (pink), VC/VS (orange), SGC (green), and OFC (blue). Fiber tracts (color coded by orientation) show putative structural connections between candidate pairs of stimulation and sensing contacts (VC/VS-AMY, VC/VS-OFC, SGC-AMY, OFC-AMY) from deterministic tractography using 3 mm ROIs centered on each contact. Tractography parameters were the same for all pairs: minimum FA = 0.1; minimum fiber length = 80 mm; maximum angulation = 20 degrees.

Extended Data Fig. 2 | Overall Approach to Stimulation and Sensing Target Selection. Multimodal method for personalized responsive stimulation multi-lead targeting began with clinical mapping to identify candidate sites where stimulation reliably led to symptom improvement across a range of doses and symptom severity states. Candidate sensing locations were identified by pairing resting state neural activity with symptom severity ratings to identify spectral power biomarkers that correlated with depression. The relationship between candidate stimulation and sensing targets were then tested using three approaches. First, effective network connectivity was assessed by examining the evoked response at nodes across the network due to single pulse stimulation at candidate targets. Second, structural connectivity between candidate contact pairs was assessed using tractography. Influential tracts were identified to help with retargeting during implantation of chronic stimulation device. Finally, the feasibility of closed-loop control was assessed by examining the effect of stimulation in candidate stimulation sites on putative biomarkers identified in candidate sensing locations. This personalized approach enabled us to identify one best stimulation and sensing target pair which were then utilized for the implantation of the RNS System and delivery of closed-loop neurostimulation therapy.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed	
☐	☒	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☐	☒	A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☒	☐	A description of all covariates tested
☐	☒	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☐	☒	For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☒	☐	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	BrainLab iPlan Stereotaxy 3.0, Python 3.5 and 3.7, FSL 6.0, NeuroPace Programmer software v1.8.0.21
Data analysis	The code and data used to produce the results and figures in this paper are available at https://github.com/ScangosLab/closed_loop_mdd

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

The data that support the findings in this report are available within the report itself, the source data, and within our publicly available GitHub Repository. Raw neural signals are freely available from the corresponding author upon request.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences ☐ Behavioural & social sciences ☐ Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/documents/nr-reporting-summary-flat.pdf

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	The sample size is N=1 in this case report.
Data exclusions	No data relevant to the case report was excluded.
Replication	All code was reviewed for accuracy by at least 2 people. All analyses were reproduced successfully. Code to reproduce the figures and analyses are available at: https://github.com/ScangosLab/closed_loop_mdd
Randomization	The data is not randomized as it is a n=1 case-report.
Blinding	The patient was blinded during the sham controlled stimulation studies. Investigators were usually but not always blinded. Blinding was broken during some sessions for safety reasons. We have subsequently added a second physician to each session so that blinding can be maintained.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Human research participants

Policy information about studies involving human research participants

Population characteristics	The patient was a 36 yo woman with severe treatment resistant depression.
Recruitment	The patient contacted our center about participation in a clinical trial of closed-loop DBS (PRESIDIO trial). The patient's physician had heard about the trial and brought it up to the patient in her clinic appointment. She then contacted us about the possiblity of participating. Patients who choose to participate in this study may have a higher tolerance for risk, have more medical knowledge, or have stronger personality disorder traits. They may be more affluent with greater access to or ability to use the internet, or psychiatrists at academic centers who know more about brain stimulation as a treatment option. Due to the inclusion criteria, participants may have depression characterized by greater mood reactivity. As a result, it is possible that closed-loop therapy may be successful only for certain types of depression.
Ethics oversight	The United States Food and Drug Administration (FDA) and the Institutional Review Board (IRB) at University of California, San Francisco approved this protocol. We also work with a neurologist who specializes in ethics of deep brain stimulation.

Note that full information on the approval of the study protocol must also be provided in the manuscript.

View publication stats

Clinical data

Policy information about clinical studies

All manuscripts should comply with the ICMJE guidelines for publication of clinical research and a completed CONSORT checklist must be included with all submissions.

Clinical trial registration	NCT04004169
Study protocol	Please see https://clinicaltrials.gov/ct2/show/NCT04004169. We can provide the study protocol upon reasonable request.
Data collection	Data were collected and analyzed between October 2019 and Jan 2021. Data were collected at the University of California, San Francisco School of Medicine. Specifically, they were collected in a laboratory setting at Langley Porter Psychiatric Hospital and Clinic and in the Epilepsy Monitoring Unit at Moffitt-Long Hospital. Self-report mood ratings were also collected by the patient at home.
Outcomes	The primary and secondary outcomes were pre-defined in our protocol that was submitted to the U.S. Food and Drug Administration and Institutional Review Board at University of California, San Francisco. The measures were logged in ClinicalTrials.gov (https://clinicaltrials.gov/ct2/show/NCT04004169) prior to enrollment of our first subject. We selected the Montgomery Asberg Depression Rating Scale (MADRS) as our primary outcome measure because it is one of the most widely used measures of depression in clinical trials. We additionally utilized visual analog scales and a 6-question version of the Hamilton Depression Rating Scale because these scales have been used previously to assess depression symptoms on a shorter timescale. The MADRS scale was administered by a physician. The remaining scales were administered using RedCap on an iPad in the laboratory or at home. Scores and time of administration were downloaded from RedCap onto a secure server where neural data was also stored.

An *in vivo* correlate of exercise-induced neurogenesis in the adult dentate gyrus

Contributed by Fred H. Gage, December 30, 2006 (sent for review November 26, 2006)

With continued debate over the functional significance of adult neurogenesis, identifying an *in vivo* correlate of neurogenesis has become an important goal. Here we rely on the coupling between neurogenesis and angiogenesis and test whether MRI measurements of cerebral blood volume (CBV) provide an imaging correlate of neurogenesis. First, we used an MRI approach to generate CBV maps over time in the hippocampal formation of exercising mice. Among all hippocampal subregions, exercise was found to have a primary effect on dentate gyrus CBV, the only subregion that supports adult neurogenesis. Moreover, exercise-induced increases in dentate gyrus CBV were found to correlate with postmortem measurements of neurogenesis. Second, using similar MRI technologies, we generated CBV maps over time in the hippocampal formation of exercising humans. As in mice, exercise was found to have a primary effect on dentate gyrus CBV, and the CBV changes were found to selectively correlate with cardiopulmonary and cognitive function. Taken together, these findings show that dentate gyrus CBV provides an imaging correlate of exercise-induced neurogenesis and that exercise differentially targets the dentate gyrus, a hippocampal subregion important for memory and implicated in cognitive aging.

hippocampus | *in vivo* imaging | cerebral blood volume | angiogenesis

The hippocampal formation, a brain circuit made up of separate but interconnected subregions (1), is vital for memory function (2) and is targeted by the aging process (3). The dentate gyrus is the only hippocampal subregion that supports neurogenesis in the adult brain (4–6). Nevertheless, because neurogenesis can only be assessed in postmortem tissue, its functional significance remains undetermined. With this limitation in mind, we have explored different imaging approaches applicable to rodents and humans that might provide an *in vivo* correlate of neurogenesis.

Although imaging radioligands designed to bind newly dividing cells is an attractive approach, positron emission tomography imaging suffers inherently poor resolution and cannot visualize the dentate gyrus. Additionally, radiolabeling newborn cells introduces potential safety concerns. For these reasons, we have focused on MRI technologies instead. Notably, a coupling has been established between neurogenesis and angiogenesis (7, 8). The process of angiogenesis, in turn, gradually gives rise to the formation of new blood vessels, increasing regional microvascular density (9–12). Importantly, vascular density can be measured *in vivo* with imaging techniques that map regional blood volume. Numerous studies have established a tight relationship between angiogenesis and regional blood volume (13–17), including in the brain where regional angiogenesis is coupled to regional cerebral blood volume (CBV) (18–26).

Because CBV can be measured with MRI, we hypothesized that a regionally selective increase in hippocampal CBV might provide an imaging correlate of neurogenesis. This hypothesis was tested in mice in which *in vivo* imaging and postmortem analysis can be performed on the same subjects. We used an MRI approach that can generate hippocampal CBV maps repeatedly and safely over time in mice while simultaneously assessing multiple hippocampal subregions (27). We exploited the capabilities of this approach to establish how hippocampal CBV maps change during physical exercise, a potent stimulant of dentate gyrus neurogenesis (28), and tested whether CBV changes correlate with postmortem measurements of neurogenesis. Once these findings were established in mice, we were interested in determining how exercise affects the hippocampal CBV maps of humans. To accomplish this goal, we first optimized an MRI approach (29) previously shown to be capable of generating hippocampal CBV maps in non-human primates (30) and then charted exercise-induced CBV changes in the human hippocampal formation.

Results

Exercise Selectively Increases Dentate Gyrus CBV in Mice and Correlates with Neurogenesis. In designing our experimental protocol, we were guided by the observation that angiogenesis-induced sprouting of new blood vessels progresses through different stages, forming gradually over time (9). Accordingly, mice were allowed to exercise for 2 weeks, the period during which neurogenesis reaches its maximum increase, and bromodeoxyuridine (BrdU), a marker of newly born cells, was injected daily during the second week. To capture the predicted delayed effect in CBV, mice were kept alive for 4 more weeks, then killed and processed for BrdU labeling. Hippocampal CBV maps (Fig. 1*b*) assessing the entorhinal cortex, the dentate gyrus, and the CA3 and CA1 subfields were generated four times over the 6-week experiment: at preexercise baseline and at weeks 2, 4, and 6. A control group following the identical protocol but without exercise was imaged in parallel.

A repeated-measure ANOVA was used to analyze the imaging data set (Fig. 1*a*). A group–time interaction was found only for the dentate gyrus, showing that exercise was associated with a selective increase in dentate gyrus CBV ($F = 5.0$, $P = 0.034$). As shown by simple contrasts, the effect was driven by a maximum increase that emerged 2 weeks after the cessation of exercise, from week 2 to week 4 ($F = 5.9$, $P = 0.021$) (Fig. 1*a*). The entorhinal cortex was the only other hippocampal subregion whose CBV increased appreciably over time, although not achieving statistical significance (Fig. 1*a*). Although exercise might potentially affect CBV by increasing metabolism and cerebral blood flow, previous studies (31, 32) have shown that exercise-induced changes in metabolism should manifest during, not after, the exercise regimen. Thus, the observed spatiotemporal profile with which CBV emerged fits better with a model of exercise-induced angiogenesis in the dentate gyrus.

In agreement with previous studies (33), the exercise group was found to have greater BrdU labeling compared with the nonexercise group ($F = 9.8$, $P = 0.004$) (Fig. 2*a*). More than 90% of

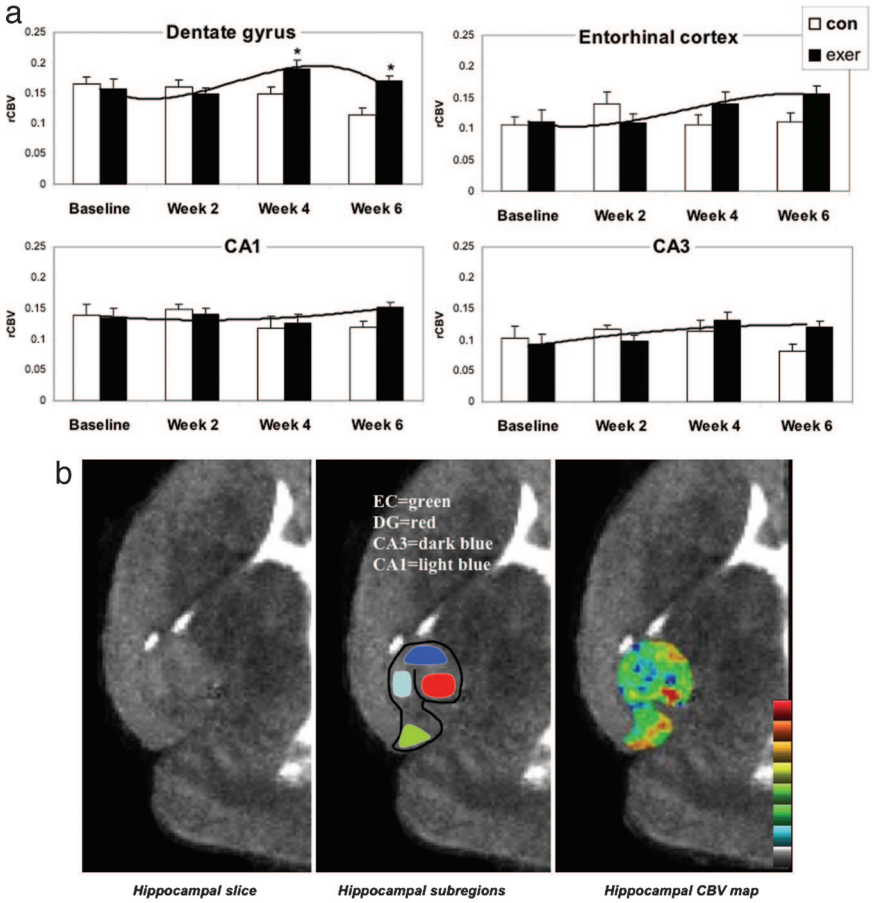

Fig. 1. Exercise selectively increases dentate gyrus CBV in mice. (*a*) Exercise had a selective effect on dentate gyrus CBV. Bar graphs show the mean relative CBV (rCBV) values for each hippocampal subregion in the exercise group (filled bars) and the nonexercise group (open bars) over the 6-week study. The dentate gyrus was the only hippocampal subregion that showed a significant exercise effect, with CBV peaking at week 4, whereas the entorhinal cortex showed a nonsignificant increase in CBV. (*b*) An individual example. (*Left*) High-resolution MRI slice that visualizes the external morphology and internal architecture of the hippocampal formation. (*Center*) Parcellation of the hippocampal subregions (green, entorhinal cortex; red, dentate gyrus; dark blue, CA3 subfield; light blue, CA1 subfield). (*Right*) Hippocampal CBV map (warmer colors reflect higher CBV).

BrdU-positive cells colabeled for NeuN, a neuron-specific marker (Fig. 2*a*). To examine the relationship between neurogenesis and CBV, the repeated-measures model was again used and included BrdU as a covariate. A significant time-by-BrdU interaction was observed only for dentate gyrus CBV ($F = 3.3$, $P = 0.039$), driven primarily by changes from week 2 to week 4 ($F = 8.8$, $P = 0.006$). As shown by a direct analysis, this effect reflected a positive correlation between BrdU and changes in CBV from week 2 to week 4 ($\beta = 0.58$, $P = 0.001$) (Fig. 2*b*). Of note, when BrdU was included as a covariate in the ANOVA, the group–time effect observed in the dentate gyrus was no longer significant, confirming that neurogenesis accounted for the exercise effect on CBV. Visual inspection of the relationship between changes in dentate gyrus CBV and BrdU (Fig. 2*b*) suggested that a quadratic vs. a linear model better characterized the relationship, which was confirmed by curve estimation analysis (linear model, $R^2 = 0.34$ and $P = 0.001$; quadratic model, $R^2 = 0.59$ and $P < 0.0001$). Thus, the association between changes in dentate gyrus CBV and BrdU exists primarily when CBV increases with exercise (Fig. 2*b*). Finally, to test whether neurogenesis was required for the observed increases in dentate gyrus CBV we relied on a previously described x-irradiation approach that selectively blocks dentate gyrus neurogenesis (55). Four mice received x-irradiation, and three mice were sham controls. After a 3-month recovery period, all mice were imaged by using the exercise protocol. A repeated-measure ANOVA applied to the CBV data set revealed a group (x-ray vs. sham)-by-time interaction only for the dentate gyrus ($F = 7.6$, $P = 0.04$), showing that irradiation blocked the exercise-induced increases in CBV [supporting information (SI) Fig. 5].

Exercise Selectively Increases Dentate Gyrus CBV in Humans and Correlates with Aerobic Fitness and Cognition. Once we established that dentate gyrus CBV provides a correlate of exercise-induced neurogenesis, we were interested in testing whether this effect is observed in exercising humans. CBV maps of the human hippocampal formation were generated by using our previously reported MRI approach, specifically tailored for imaging the primate hippocampal formation (30). Eleven healthy subjects (mean age = 33, ranging from 21–45 years; two males and nine females) participated in the study, completing a 3-month aerobic exercise regimen. Hippocampal CBV maps were generated before and after exercise. CBV values were reliably measured for all hippocampal subregions, except the CA3 subregion (Fig. 3*b*). Compared with experimental animals, in humans it is impossible to control the interindividual differences in physical activity performed during daily life. Therefore, before and after exercise, we measured the maximum volume of oxygen consumption (VO_2max), the gold standard measure of exercise-associated aerobic fitness (34, 35) to quantify individual differences in degree of exercise. Cognitive performance was assessed by using a modified Rey Auditory Verbal Learning Test (36), whose design allows cognition to be tested across different learning trials and during delayed recall, recognition, and source

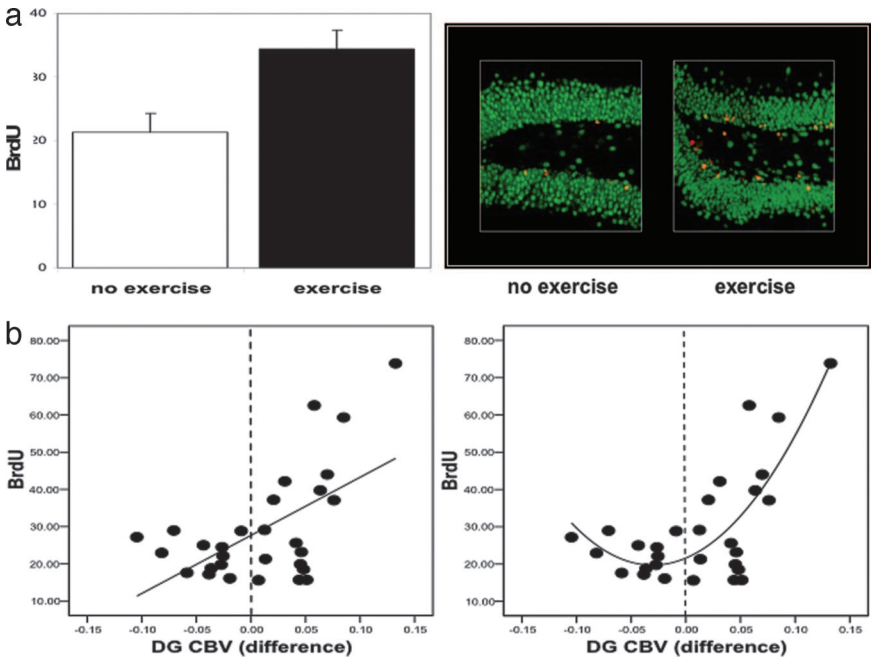

Fig. 2. Exercise-induced increases in dentate gyrus CBV correlate with neurogenesis. (*a*) (*Left*) Exercising mice were found to have more BrdU labeling compared with the no-exercise group. (*Right*) As shown by confocal microscopy, the majority of the new cells were colabeled with NeuN (red, BrdU labeling; green, NeuN; yellow, BrdU/NeuN double labeling). (*b*) (*Left*) A significant linear relationship was found between changes in dentate gyrus CBV and BrdU labeling. (*Right*) A quadratic relationship better fits the data. The vertical stippled line in each plot splits the *x* axis into CBV changes that decreased (left of line) versus those that increased (right of line) with exercise.

memory. Ten subjects were cognitively assessed after exercise, eight of whom were assessed at preexercise baseline.

A repeated-measures ANOVA used to analyze the imaging data showed that the dentate gyrus was the only hippocampal subregion whose CBV significantly increased over time ($F = 12$, $P = 0.006$) (Fig. 3*a*). As in mice, the entorhinal cortex was the only other hippocampal subregion whose CBV increased appreciably over time, although not achieving statistical significance ($F = 4.3$, $P = 0.064$) (Fig. 3*a*). As a group, VO_2max values significantly increased over time ($F = 11.6$, $P = 0.007$) (Fig. 4*a*), and, to confirm that the imaged changes were directly related to exercise and not simply caused by a test–retest effect, we found that individual differences in dentate gyrus CBV were correlated to individual changes in VO_2max ($\beta = 0.662$, $P = 0.027$) (Fig. 4*b*). Importantly, a correlation between CBV and VO_2max was not observed for any other hippocampal subregion, including the entorhinal cortex (Fig. 4*b*), confirming that exercise has a selective effect on dentate gyrus CBV.

Cognitively, individuals performed significantly better on trial 1 learning ($F = 7.0$, $P = 0.027$) after exercise, with a trend toward improvement on all-trial learning ($F = 5.0$, $P = 0.053$) and delayed recall ($F = 5.0$, $P = 0.057$). There was no effect on delayed recognition ($F = 0.19$, $P = 0.67$) or source memory ($F = 0.15$, $P = 0.25$) (Fig. 4*a*). To test that cognitive improvement was related to exercise *per se*, we found that individual changes in trial 1 learning were correlated with individual changes in VO_2max ($\beta = 0.660$, $P = 0.037$). However, because only 8 of the 10 subjects completed preexercise cognitive testing, we repeated the analysis with postexercise cognitive performance scores. Again, we found that changes in VO_2max correlated exclusively with postexercise trial 1 learning ($\beta = 0.70$, $P = 0.026$) (Fig. 4*b*). Additional analyses showed that the correlation between changes in VO_2max and cognition was selective to trial 1 learning (Fig. 4*b*), thereby confirming that, despite apparent increases in other cognitive measures (i.e., delayed recognition, as shown in Fig. 4*a*), this particular measure was selectively influenced by exercise.

Finally, we examined the relationship between cognition and CBV. Among all hippocampal subregions, the correlation between improvements in trial 1 performance and increases in dentate gyrus CBV was the only one that trended toward significance ($\beta = 0.62$, $P = 0.052$). Because of the missing preexercise data, we repeated all of the analyses comparing changes in CBV with postexercise cognition, finding an exclusive correlation between postexercise trial 1 learning and dentate gyrus CBV ($\beta = 0.63$, $P = 0.026$) (Fig. 4*b*).

Discussion

Taken together, our findings show that, within the hippocampal formation, exercise targets the dentate gyrus with regional selectivity. In addition, our results identify that, in mice, dentate gyrus CBV is an imaging correlate of exercise-induced neurogenesis.

Because of its pleiotropic effect on the brain (37, 38), the subregional selectivity that exercise was found to have within the hippocampal formation was an unexpected finding. This observation is particularly interesting in light of studies suggesting that the dentate gyrus is a hippocampal subregion differentially vulnerable to the aging process, as shown in humans (39, 40), nonhuman primates (30, 41), and rodents (30, 42), and that dentate gyrus dysfunction contributes to cognitive aging (30, 40). Interestingly, a growing number of studies have established that exercise ameliorates age-related cognitive decline (43–46). Thus, the effect that exercise was observed to have on the dentate gyrus likely contributes to the reported cognitive benefits exercise has on the aging brain.

Because neurogenesis couples with angiogenesis (7, 8) and angiogenesis, in turn, couples with CBV (18–26), we hypothesized that measures of CBV might provide an *in vivo* correlate of neurogenesis. This hypothesis is based in part on our previous findings that exercise increases both neurogenesis and angiogenesis in young adult rodents (43). We have confirmed this prediction with our high-resolution MRI techniques, which are capable of assessing individual hippocampal subregions, showing that dentate gyrus

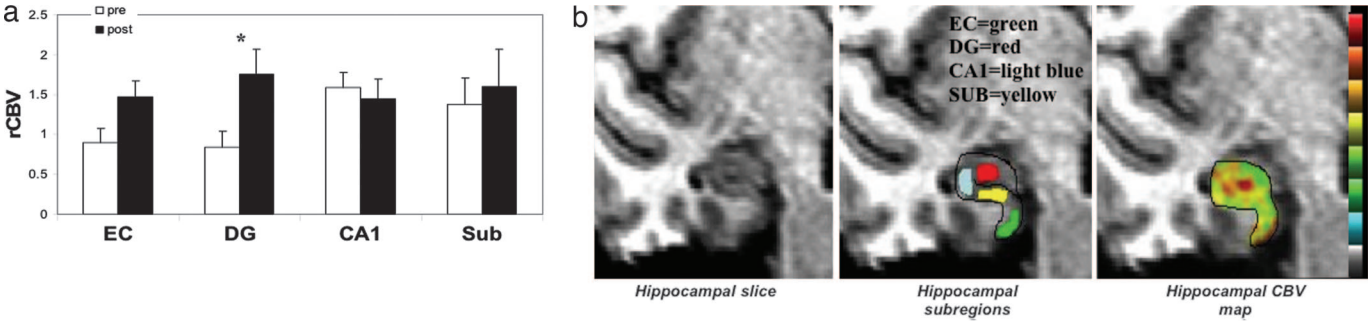

Fig. 3. Exercise selectively increases dentate gyrus CBV in humans. (*a*) Exercise had a selective effect on dentate gyrus CBV. Bar graph shows the mean relative CBV (rCBV) values for each hippocampal subregion before exercise (open bars) and after exercise (filled bars). As in mice, the dentate gyrus was the only hippocampal subregion that showed a significant exercise effect, whereas the entorhinal cortex showed a nonsignificant increase in CBV. (*b*) An individual example. (*Left*) High-resolution MRI slice that visualizes the external morphology and internal architecture of the hippocampal formation. (*Center*) Parcellation of the hippocampal subregions (green, entorhinal cortex; red, dentate gyrus; blue, CA1 subfield; yellow, subiculum). (*Right*) Hippocampal CBV map (warmer colors reflect higher CBV).

CBV selectively correlates with underlying neurogenesis in mice. Blocking the exercise-induced CBV effect with irradiation, a neurogenesis suppressant, further confirms that neurogenesis underlies the observed increases in CBV. However, in the absence of direct measurements, we have not confirmed that angiogenesis is the intermediate factor that accounts for this relationship. Mechanistically, there are many molecules that may be mediating the exercise-induced coupling between neurogenesis and angiogenesis (47), including VEGF (8) or exercise-induced changes in BDNF (48).

The remarkable similarities between the exercise-induced CBV changes in the hippocampal formation of mice and humans suggest that the effect is mediated by similar mechanisms. Of course, in contrast to mice, it is impossible to directly confirm whether the changes in dentate gyrus CBV observed in humans are a reflection of neurogenesis. Nevertheless, previous rodent studies have shown that levels of neurogenesis are coupled with individual differences in degree of exercise (28). Therefore, together with the cross-species similarities on hippocampal CBV, the observation that exercise-induced changes in dentate gyrus CBV correlate with VO_2max supports the interpretation that the human effect is mediated, at least in part, by neurogenesis.

In any case, our results show that *in vivo* imaging can predict levels of neurogenesis in living mice. Furthermore, as demonstrated, the MRI technologies used in these studies are capable of measuring meaningful changes in dentate gyrus CBV over time in both humans and mice. By providing evidence in support of exercise-induced neurogenesis and by introducing the tools needed to achieve this goal, this study shows that it is possible to isolate the specific profile of cognitive changes that are neurogenesis-dependent. Furthermore, the imaging tools presented here are uniquely suited to investigate potential pharmacological modulators of neurogenesis, testing their role in treating depression (49) and in ameliorating the cognitive decline that occurs in all of us as we age (43, 50).

Methods

Exercise. ***Mice.*** A total of 46 C57BL/6 mice (7 weeks old) were used (23 exercising and 23 nonexercising animals). The experimental mice were placed in cages with running wheels (Lafayette Instrument Company, Lafayette, IN). The animals ran voluntarily for 2 weeks. MRI images were acquired at the following time points: week 0 (baseline), week 2 (when exercise was stopped), week 4, and week 6. The thymidine analog BrdU marker was injected i.p. for 7 consecutive days (60 $mg \cdot kg^{-1} \cdot day^{-1}$) during the second week of the experiment. At week 6, the animals were anesthetized and killed in accordance with institutional guidelines.

Human. Eleven subjects (mean age, 33 ranging from 21–45 years; 2 males and 9 females) who fulfilled the American Heart Association criteria for below-average aerobic fitness (VO_2max, <43 for men and <37 for women) were recruited (51). The 11 enrolled subjects engaged in an exercise training protocol for 12 weeks at Columbia University Fitness Center at a frequency of four times a week. Each exercise session lasted ≈1 h: 5 min of low-intensity warm-up on a treadmill or stationary bicycle, 5 min of stretching, 40 min of aerobic training, and 10 min for cool down and stretching. During the 40 min of aerobic activity, subjects were permitted to select from cycling on a stationary ergometer, running on a treadmill, climbing on a StairMaster, or using an elliptical trainer.

VO_2max was measured by a graded exercise test on an Ergoline 800S electronic-braked cycle ergometer (SensorMedics, Anaheim, CA). Each subject began exercising at 30 W for 2 min, and the work rate was continually increased by 30 W each 2 min until VO_2max criteria (respiratory quotient of ≥ 1.1, increases in ventilation without concomitant increases in VO_2, maximum age-predicted heart rate, and/or volitional fatigue) were reached. Minute ventilation was measured by a pneumotachometer connected to a FLO-1 volume transducer module (Physio-Dyne Instrument Corporation, Quogue, NY). Percentages of expired oxygen (O_2) and carbon dioxide (CO_2) were measured by using a paramagnetic O_2 analyzer and an infrared CO_2 analyzer connected to a computerized system (MAX-1; Physio-Dyne Instrument Corporation). These analyzers were calibrated against known medical grade gases. The highest VO_2 value attained during the graded exercise test is considered VO_2max.

In Vivo* Imaging.** ***Mice. Mice were imaged with a 9.4-T Bruker scanner (AVANCBV 400WB spectrometer; Bruker NMR, Billerica, MA) by following a previously described protocol (27). Briefly, axial T2-weighted images were optimally acquired with a fast sequence (time to repeat/effective echo time = 2,000 ms/70 ms; 30-mm i.d. birdcage radio frequency probe; shielded gradient system, 100 g/cm; rapid acquisition with relaxation enhancement factor, 16; field of view, 19.6 mm; acquisition matrix, 256 × 256; no. of slices, 8; slice thickness, 0.6 mm; slice gap, 0.1 mm; number of excitations, 28). Five sets of images were acquired sequentially, each requiring 16 min. The first two sets were precontrast. Gadodiamide was then injected (13 mmol/kg i.p.) through a catheter placed intraperitoneally before imaging. The last three sets corresponded to the postcontrast images. To prevent head motion and reduce anxiety, the animals were anesthetized with isoflurane gas [1.5% (vol/vol) for maintenance at 1 liter per minute of air flow) via a nose cone. Isoflurane was chosen because it induces minimal cerebral hemodynamic change (52). Monitoring of the heart rate, respiratory rate, and oxygen saturation was performed during the whole

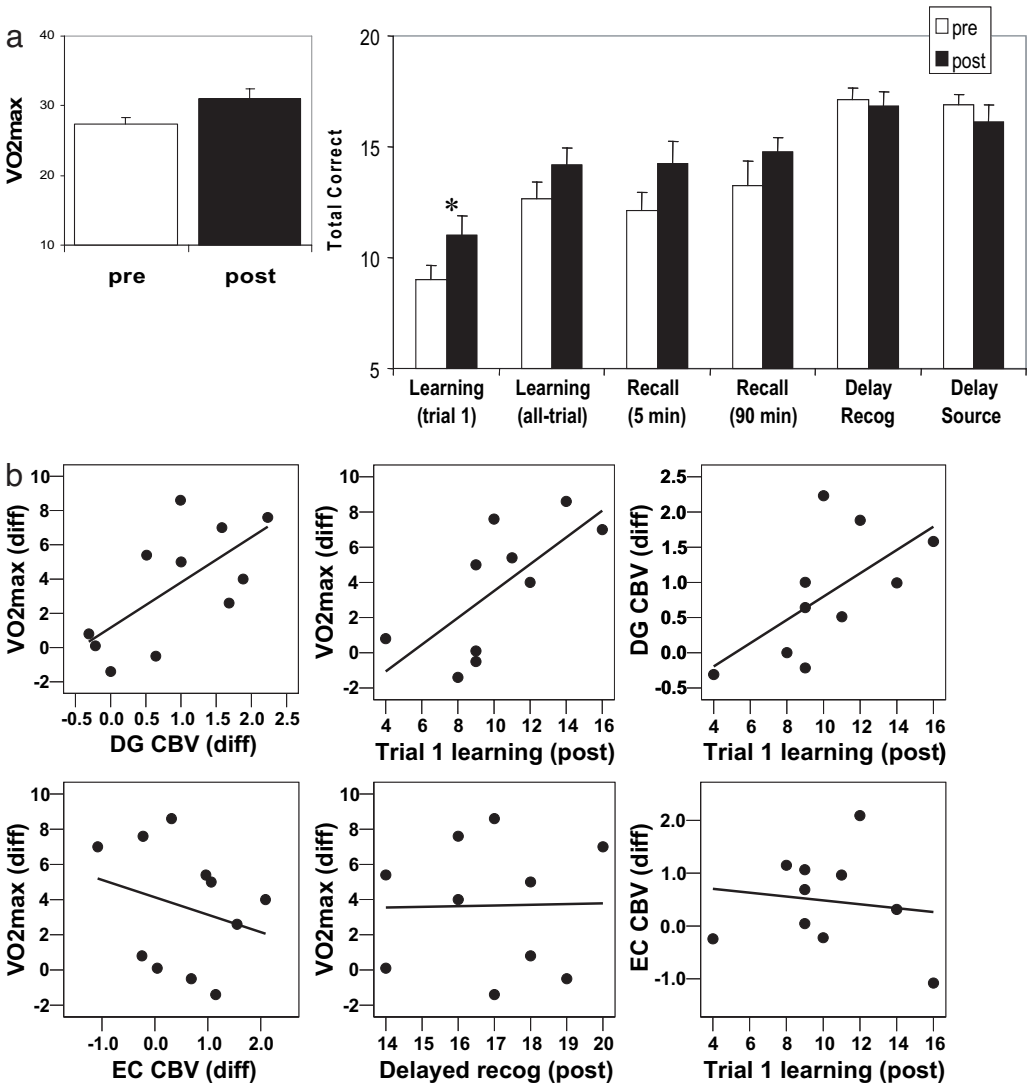

Fig. 4. Exercise-induced increases in dentate gyrus CBV correlate with aerobic fitness and cognition. (*a*) (*Left*) VO_2max, the gold-standard measure of exercise-induced aerobic fitness, increased after exercise. (*Right*) Cognitively, exercise has its most reliable effect on first-trial learning of new declarative memories. (*b*) (*Left*) Exercise-induced changes in VO_2max correlated with changes in dentate gyrus (DG) CBV but not with other hippocampal subregions, including the entorhinal cortex (EC), confirming the selectivity of the exercise-induced effect. (*Center*) Exercise-induced changes in VO_2max correlated with postexercise trial 1 learning but not with other cognitive tasks, including delayed recognition. (*Right*) Postexercise trial 1 learning correlated with exercise-induced changes in dentate gyrus CBV but not with changes in other hippocampal subregions, including the entorhinal cortex.

procedure. Relative CBV was mapped as changes of the transverse relaxation rate (ΔR^2) induced by the contrast agent. When the contrast agent reaches uniform distribution, CBV maps can be measured from steady-state T2-weighted images as CBV $\propto \Delta R^2 = \ln(S_{pre}/S_{post})/TE$, where TE is the effective echo time, S_{pre} is the signal before the contrast administration, and S_{post} is the signal after the contrast agent reaches steady-state. To control for differences in levels of contrast administration, cardiac output, and global blood flow, the derived maps were normalized to the maximum 4-pixel signal value of the posterior cerebral vein. Visualized anatomical landmarks were used together with standard atlases to identify the localization of four hippocampal subregions: the dentate gyrus, the CA3 subfield, the CA1 subfield, and the entorhinal cortex (53). The normalized CBV measurements from each subregion were used for group data analysis.

Human. Subjects were imaged with a 1.5-T scanner Intera scanner (Philips, Amsterdam, The Netherlands). As previously described (30), coronal T1-weighted images (repetition time, 20 ms; echo time, 6 ms; flip angle, 25°; in-plane resolution, 0.86 × 86 mm; slice thickness, 4 mm) were acquired oriented perpendicular to the hippocampal long-axis before and 4 min after i.v. administration of the contrast gadolinium (0.1 mmol/kg). The difference between precontrast and postcontrast images was used to access the regional CBV map. To control for differences in levels of contrast administration, cardiac output, and global blood flow, the derived differences in signal intensity were normalized to the maximum 4-pixel signal value of the sagittal sinus (29). For each subject, the precontrast scan was used to identify the slice with the best visualization of the external morphology and internal architecture of the hippocampal formation. Visualized anatomical landmarks were used together with standard atlases to identify the general locale of four subregions: the dentate gyrus, the CA1 subfield, the subiculum, and the entorhinal cortex (30). The normalized CBV measurements from each subregion were used for group data analysis.

Microscopy. ***Immunohistochemistry.*** Free-floating, 40-μm coronal sections were used in the determination of BrdU labeling. DNA denaturation was conducted by incubation for 1 h at 2 M HCl at

37°C, followed by washing in boric buffer (pH 8.5). After washing, sections were incubated for 30 min in 10% H_2O_2 to eliminate endogenous peroxidases. After blocking with 3% normal donkey serum in 0.2% Triton X-100, sections were incubated with monoclonal anti-BrdU (1:600; Roche, Basel, Switzerland) overnight at 4°C. Sections were then incubated for 1 h at room temperature with the secondary antibody (biotinylated donkey anti-mouse; Jackson ImmunoResearch Laboratories, West Grove, PA) followed by amplification with an avidin–biotin complex (Vector Laboratories, Burlingame, CA), and visualized with diaminobenzidine (Sigma, St. Louis, MO). For double-immunolabeling, free-floating sections were incubated in a mixture of primary antibodies, anti-BrdU (1:600; Roche), and anti-NeuN (1:500; Chemicon, Temecula, CA), raised in different species overnight. For visualization, Alexa Fluor-conjugated appropriate secondary antibodies (1:300; Molecular Probes, Eugene, OR) raised in goats were used for 1 h at room temperature. Blocking serum and primary and secondary antibodies were applied in 0.2% Triton X-100 in PBS. Sections for fluorescent microscopy were mounted on slides in VECTASHIELD (Vector Laboratories). For control of the specificity of immunolabeling, primary antibodies were omitted and substituted with appropriate normal serum. Slides were viewed with a confocal microscope [Radiance 2000 (Bio-Rad, Hercules, CA) mounted on a E800 microscope (Nikon, Tokyo, Japan)]. The images presented are stacks of six to 16 optical sections (step, 1 mm) that were collected individually (in the green and red channels) or simultaneously with precaution against cross-talk between channels. The images were processed with PhotoShop 7.0 (Adobe Systems, San Jose, CA) without contrast and brightness changes in split images.

Quantitation of BrdU labeling. Every sixth section throughout the hippocampus was processed for BrdU immunohistochemistry. Ten sections were used for each animal. All BrdU-labeled cells in the dentate gyrus (granule cell layer and subgranular zone) were counted under a light microscope by an experimenter blinded to the study code. The average number of BrdU-labeled cells was then derived for each animal.

Cognitive testing. Declarative memory was measured with a version of the Rey Auditory Verbal Learning Test (36) modified to increase variability in memory performance among healthy young adults. Twenty nonsemantically or phonemically related words were presented over three learning trials in which the test administrator read the word list and the subject free-recalled as many words as possible. Administration of the three learning trials was immediately followed by one learning trial of a distracter list and then a short delayed free recall of the initial list. After a 90-min delay period, subjects were asked to freely recall words from the initial list and then to freely recall items from the distracter list. After a 24-hr delay period, subjects were contacted by telephone and asked to freely recall items from the initial list and then from the distracter list. They were then administered a forced-choice recognition trial in which they were required to identify the 20 words from the initial learning trial among semantically and phonemically related words, as well as words from the distracter trial. Finally, a source memory trial was administered in which subjects were read a list containing only words from the initial learning list and from the distracter list and were asked to identify from which list each word came. Two forms of the verbal learning test were created, and the administration order was counterbalanced. As in previous studies (54), we measured words correctly recalled on the first trial of the initial learning trials, the average number of words recalled across the three learning trials, the number of words from the initial learning trial that were correctly recalled after a short delay (<5 min), the number of words from the initial learning trial that were correctly recalled after a 90-min delay, the number of items correctly identified on the recognition trial, and the correct number of items identified on the source memory trial.

Differential Diagnosis of Cushing's Syndrome

ABSTRACT

The differential diagnosis of Cushing's syndrome requires careful multidisciplinary interaction with a number of specialities, co-ordinated through endocrine centres with good experience of this condition. It is essential that the diagnosis of Cushing's syndrome be fully established before differential diagnosis is attempted. The endocrinologist needs to be aware of the pitfalls and advantages of the tests in use. We discuss the approach to the differential diagnosis of this challenging condition. **(Arq Bras Endocrinol Metab 2007;51/8:1199-1206)**

ONCE THE DIAGNOSIS of the hypercortisolism of Cushing's syndrome is firmly established, attention can be turned to establishing the cause. This is an important point as all the tests used in the differential diagnosis depend on the prior demonstration of hypercortisolism. If there is any doubt diagnostic tests should be repeated, if needed on several occasions, before continuing on the differential diagnostic pathways. We give an overview of the differential diagnostic pathway, of which the individual parts are also discussed in detail in other articles in this edition.

CAUSES OF CUSHING'S SYNDROME

To understand the limitations of the various tests used in the differential diagnosis of Cushing's syndrome it is important to know the approximate likelihood of the cause. Endogenous Cushing's syndrome is com-

Recebido em 30/07/07
Aceito em 10/08/07

moner in women than men and is divided into adrenocorticotrophin (ACTH)-dependent, and ACTH-independent, causes (table 1). Overall, ACTH-dependent causes account for approximately 80–85% of cases, and of these 80% are due to pituitary adenomas (*Cushing's disease*), with the remaining 20% or so due to the ectopic ACTH syndrome (1,2). Ectopic ACTH secretion is most commonly from small cell carcinoma of the lung and bronchial carcinoid tumours, but may also occur with almost any endocrine tumour from many different organs (e.g. phaeochromocytoma, pancreatic neuroendocrine tumours, gut carcinoids) (table 2) (3,5). When the ectopic ACTH syndrome is due to small cell carcinoma of the lung it may have a rapid onset with severe features of muscle weakness, but without the classical Cushing's phenotype. In contrast, the clinical phenotype (and some biochemical features) of carcinoid tumours may be indistinguishable from that of Cushing's disease (3-6). In ectopic ACTH syndrome when the source of ACTH is apparent on simple imaging, this is referred to as the 'overt' ectopic ACTH syndrome and may be due to rapidly progressive small cell lung cancer or a more indolent source. If the source of ectopic ACTH is found only after extensive imaging this is referred to as 'covert' ectopic ACTH, whilst if the source is not found despite extensive imaging, this is termed 'occult'.

ACTH-independent Cushing's syndrome is due in most cases to a unilateral tumour: adrenal adenoma in 60% and carcinoma in 40% of cases. Very rare adrenal causes of Cushing's syndrome are ACTH-independent macronodular adrenal hyperplasia (AIMAH), primary pigmented nodular adrenal disease (PPNAD) (either as isolated disease or as part of Carney complex), and the McCune Albright syndrome (2,7,8).

ESTABLISHING THE AETIOLOGY OF CUSHING'S SYNDROME (figure 1)

Measurement of plasma ACTH

The differential diagnosis of Cushing's syndrome is best done in major referral centres. Investigation will vary depending upon the availability of the biochemical tests and imaging detailed below. The first step is to measure plasma ACTH. Levels consistently below 5 pg/ml indicate ACTH-independent Cushing's syndrome. In this case the next step is imaging the adrenal glands with CT or MRI. Levels of ACTH persistently above 15 pg/ml almost always reflect ACTH-dependent pathologies and require investigation, as detailed below. Plasma ACTH values between 5–15 pg/ml need careful interpretation since some patients with Cushing's disease and adrenal pathologies may have intermediate values (2,9,10). It is essential that the sample for plasma ACTH is separated rapidly and stored at -40°C to avoid degradation and a falsely low result. A positive CRH test (see below) can be useful to demonstrate ACTH-dependent hypercortisolism in an occasional patient with Cushing's disease with low baseline ACTH plasma levels.

ACTH-independent Cushing's syndrome

When adrenal adenoma, carcinoma or AIMAH is the cause of ACTH-independent Cushing's syndrome, the anatomical cause is invariably visible on imaging with CT (11). In cases of unilateral adrenal adenomas and carcinomas causing Cushing's syndrome it is usual for the contra-lateral adrenal gland to undergo atrophy in the prolonged absence of plasma ACTH. One simple means of assessing the size of the limbs of the adrenal gland is to compare them to the adjacent crus of the diaphragm on CT — if larger than the width of the

Table 1. Aetiology of Cushing's syndrome.

diaphragm, as seen on CT, hyperplasia is possible and caution is needed to ensure that bilateral disease is not inadvertently characterised as unilateral.

In PPNAD, the adrenal glands may appear normal. Thus, in an established diagnosis of ACTH-independent Cushing's syndrome with normal appearances of the adrenal glands on imaging assessment of other features of Carney complex (lentigines, myxoma), and genetic testing for mutations of *PRKAR1A* may be of benefit as a diagnostic procedure. Exogenous glucocorticoid ingestion (especially hydrocortisone but also synthetic glucocorticoids that cross react in the cortisol assay) should also be reconsidered in this setting.

ACTH-dependent Cushing's syndrome

Overview

Differentiating between pituitary and non-pituitary sites of excess ACTH secretion may be a considerable challenge in clinical endocrinology. Neuroendocrine (carcinoid) tumours may be clinically indistinguishable from Cushing's disease. Moreover, as they are usually small they are frequently difficult to identify with imaging, especially if radiological (pituitary, thoracic, pancreatic) "incidentalomas" complicate interpretation. It is for these reasons that biochemical evaluation is relied upon rather than imaging, to differentiate between pituitary and non-pituitary causes (1-5). It is important to note that in women with ACTH-dependent Cushing's syndrome 9 out of 10 cases will be due to Cushing's disease. It is against this pre-test likelihood that the performance of any test needs to be judged. If a patient has ACTH-dependent Cushing's syndrome, with responses *both* on dexamethasone suppression *and* CRH testing suggesting pituitary disease, and the pituitary MRI scan shows an isolated lesion of 6 mm or more, most will regard the diagnosis of Cushing's disease to have been made. A major problem is that up to 40% of patients with proven Cushing's disease have normal pituitary MRI scans (9). The results of CRH and dexamethasone tests, and pituitary MRI, should be considered together, and bilateral inferior petrosal sinus sampling (BIPSS) is usually recommended unless there is a clear diagnosis (figure 2).

Plasma potassium

High levels of cortisol may either saturate the 11β-hydroxysteroid dehydrogenase type II enzyme in the kidney, or decrease expression of this enzyme, allowing cortisol to act even more as a mineralocorticoid (12). The commonest cause of hypokalaemia is the ectopic ACTH syndrome, but it is also present in those patients with Cushing's disease with extremely high cortisol production (approximately 10% of patients) (2).

Plasma ACTH

The circulating levels of plasma ACTH are usually lower in patients with Cushing's disease compared to those with ectopic secretion. There is, however, considerable overlap and this means that the absolute levels cannot be used reliably to discriminate between groups.

DYNAMIC NON-INVASIVE TESTS

High-dose dexamethasone-suppression test (HDDST)

The high dose dexamethasone suppression tests have been in widespread use for many years. In most centres either dexamethasone 2 mg given every 6 hours for 48 hours, or a single 8 mg dose is given with serum or urinary cortisol measured at the beginning and end of the test. Measurement of serum cortisol is easier and superior to measurement of urinary free cortisol or steroid metabolites. The HDDST relies upon the relative sensitivity of pituitary corticotroph adenomas to the effects of glucocorticoids, compared to the resistance exhibited by non-pituitary tumours. Approximately 80% of patients with Cushing's disease will demonstrate suppression of the serum cortisol to a value of < 50% of the basal level (2). This is less than the pre-test likelihood of Cushing's disease, and thus, by itself, the high dose dexamethasone suppression test has little diagnostic utility (13). Moreover, in very large series we have shown that when utilising the 48-hour low-dose dexamethasone-suppression test, if there has already been the demonstration of suppression of serum cortisol by more than 30%, there is no further advantage to going on to a high dose dexamethasone suppression test (14). Therefore, overall, we would not recommend the continued routine use of the HDDST except when BIPSS is not available.

The corticotrophin-releasing hormone (CRH) test

The basis of the corticotropin-releasing hormone test is that CRH stimulates corticotroph tumour cells in the pituitary to release ACTH and hence increase serum cortisol concentrations, whilst responses are uncommon in the ectopic ACTH syndrome. This is because of the frequent expression of the CRH-1 receptor in corticotroph tumours, which is rare in

ectopic tumours. Recombinant human or ovine-sequence CRH is administered as an intravenous bolus dose of either 1 μg/kg, or in adults 100 μg IV. The ovine-sequence CRH test has a sensitivity of 93% for Cushing's disease based on ACTH responses at 15 and 30 minutes (15). Using more extensive sampling (up to 90 minutes) and a more stringent cut-off point of a 50% increment in plasma ACTH, ovine-sequence CRH had a sensitivity of 86% for Cushing's disease (16). An almost identical sensitivity is found for the human sequence peptide sampling at the same time points (17). Responses to both CRH testing and the high-dose dexamethasone suppression test are also more frequently discordant in patients with Cushing's disease secondary to a pituitary macroadenoma (18).

Desmopressin testing

Since the V3 receptor is expressed in pituitary and many ectopic tumours secreting ACTH (19-22), the desmopressin test is of limited utility in the differential diagnosis of ACTH-dependent Cushing's syndrome (23,24). Similarly, a combined test using CRH and desmopressin has been used (25), but larger series have suggested that there remains overlap between responses in patients with Cushing's disease and the ectopic ACTH syndrome (26) due to the more frequent expression of the V3 receptor in ectopic tumours.

INVASIVE TESTING

Bilateral inferior petrosal sinus sampling (BIPSS)

Sampling of the gradient of ACTH from the pituitary to the periphery is the most reliable means for discriminating between pituitary and non-pituitary sources of ACTH. When there is a central source of ACTH there is a gradient of the value of plasma ACTH compared to the simultaneous peripheral sample, since the pituitary effluent drains via the cavernous sinuses to the petrosal sinuses and then the jugular bulb. BIPSS is a highly skilled and invasive technique, requiring placement of catheters in both inferior petrosal sinuses. Catheter position and venous anatomy require confirmation by venography, as non-uniform drainage is not uncommon. The diagnostic accuracy of the test requires the administration of CRH. A basal central: peripheral ratio of > 2:1 or a CRH stimulated ratio of > 3:1 is consistent with Cushing's disease (27). The combined data for many series indicates a sensitivity and a specificity of 94% (28). Small series data have suggested that these false negative responses can be identified by simultaneous sampling of prolactin to correct values in ACTH (29,30). It is possible that falsely positive results may be caused by inadequate suppression of the normal corticotrophs and the duration and amount of hypercortisolism should be assessed prior to the test. Where CRH is unobtainable or too costly, desmopressin offers a reasonable alternative, but few patients with ectopic ACTH secretion have been studied in this way (31,32). Using both peptides during BIPSS in combination has also been recently reported and appears effective, but again few patients with ectopic ACTH have been studied (33).

In adults, BIPSS is only 70% accurate for lateralisation of the source of ACTH within the pituitary gland (2,10), but in children it may have greater accuracy for this purpose than MRI (34). Sampling from the cavernous sinuses directly does not improve accuracy (35).

Internal jugular venous sampling

Sampling from the internal jugular vein has been proposed as a simplified procedure. Direct comparison in the same patients has shown this to be inferior to BIPSS (36). One application of this test, however, may be in centres of limited sampling experience, and BIPSS (performed in a referral centre) reserved if the results are negative (37).

IMAGING

Adrenal

CT gives the best resolution of adrenal anatomy. It is important to note that in ACTH-dependent Cushing's syndrome nodules may occur and adrenal hyperplasia is not always symmetrical. This can cause diagnostic confusion with a unilateral primary adrenal cause if the biochemistry is not strictly assessed. Conversely, in 30% of Cushing's disease the adrenal glands appear normal, whilst in ectopic ACTH the adrenals are virtually always homogeneously enlarged (38).

Pituitary

Up to 40% of corticotroph adenomas causing Cushing's disease in adults are not visible on standard sequence 1.5 tesla MRI scanning (9). This fact is further complicated by a 10% rate of pituitary incidentalomas in the normal population (39), emphasising the need for careful biochemical discrimination of pituitary from non-pituitary sources of ACTH. Therefore, in the absence of a pituitary macroadenoma, an abnormal MRI is not conclusive evidence in favour of Cushing's disease.

Corticotroph tumours that are visible usually fail to enhance following gadolinium on T1-weighted imaging. The use of dynamic MRI, with the administration of intravenous contrast media and rapid sequence acquisition following this, does not improve the overall diagnostic rate. However, spoiled gradient sequences may have greater sensitivity in adults (40) and children (41).

Imaging in the ectopic ACTH syndrome

If clinical and biochemical assessments suggest a non-pituitary source of ACTH, then detailed further imaging studies are needed. Axial imaging with thin cut multi-slice CT of thorax and abdomen, and/or MRI of the thorax, has the highest detection rate for the ectopic ACTH syndrome. Small neuroendocrine tumours frequently express somatostatin receptors and may be disclosed on somatostatin receptor scintigraphy. However, while standard somatostatin scintigraphy may confirm functionality for a lesion found on axial imaging, it has only rarely been shown to disclose truly "occult" tumours that are not visible on CT (2,4,5,42-44). Using higher than standard doses of radionuclide may, in some cases, disclose lesions that were otherwise negative on imaging. In patients with recurrent disease, somatostatin scintigraphy may be useful for follow-up (45) as it has a low false-positive rate (46). Positron emission tomography (PET) with 18-flurodeoxyglucose (FDG) is of little benefit as such tumours are usually of low metabolic activity (47). The use of ^{11}C-5-hydroxytryptophan with PET has been proposed as a universal imaging technique for neuroendocrine tumours, but few patients have been studied (48) and further experience is required to determine its utility. There is also increasing interest in ^{68}Ga-octreotate PET scanning. Despite extensive investigation, the cause of ACTH may remain 'occult' in 5–15% of patients, and these require continued follow-up. Over time the number remaining undiagnosed reduces as tests are repeated, although establishing the cause occasionally may take up to 20 years of follow up (49).

CONCLUSIONS

The differential diagnosis of Cushing's syndrome requires multidisciplinary interaction with a number of specialities, co-ordinated through endocrine centres with good experience of this condition. It is essential the diagnosis of Cushing's syndrome be fully established before differential diagnosis is attempted. The endocrinologist needs to be aware of the pitfalls of the tests in use, and that these may need repeating over time if the source of ACTH is not found at initial diagnostic workup.

This contribution is part of the special series of Inaugural Articles by members of the National Academy of Sciences elected on April 30, 1996.

Contributed by Marcus E. Raichle, October 26, 2000

A baseline or control state is fundamental to the understanding of most complex systems. Defining a baseline state in the human brain, arguably our most complex system, poses a particular challenge. Many suspect that left unconstrained, its activity will vary unpredictably. Despite this prediction we identify a baseline state of the normal adult human brain in terms of the brain oxygen extraction fraction or OEF. The OEF is defined as the ratio of oxygen used by the brain to oxygen delivered by flowing blood and is remarkably uniform in the awake but resting state (e.g., lying quietly with eyes closed). Local deviations in the OEF represent the physiological basis of signals of changes in neuronal activity obtained with functional MRI during a wide variety of human behaviors. We used quantitative metabolic and circulatory measurements from positron-emission tomography to obtain the OEF regionally throughout the brain. Areas of activation were conspicuous by their absence. All significant deviations from the mean hemisphere OEF were increases, signifying deactivations, and resided almost exclusively in the visual system. Defining the baseline state of an area in this manner attaches meaning to a group of areas that consistently exhibit decreases from this baseline, during a wide variety of goal-directed behaviors monitored with positron-emission tomography and functional MRI. These decreases suggest the existence of an organized, baseline default mode of brain function that is suspended during specific goal-directed behaviors.

Functional brain imaging studies in normal human subjects with positron-emission tomography (PET) and functional MRI (fMRI) have consistently revealed expected task-induced increases in regional brain activity during goal-directed behaviors (for brief reviews see refs. 1 and 2). These changes are detected when comparisons are made between a task state, designed to place demands on the brain, and a control state, with a set of demands that are uniquely different from those of the task state.

Researchers have also frequently encountered task-induced decreases in regional brain activity even when the control state consists of lying quietly with eyes closed or passively viewing a stimulus. Whereas cortical increases in activity have been shown to be task specific and, therefore, vary in location depending on task demands, many decreases (Fig. 1) appear to be largely task independent, varying little in their location across a wide range of tasks (3). This consistency with which certain areas of the brain participate in these decreases made us wonder whether there might be an organized mode of brain function that is present as a baseline or default state and is suspended during specific goal-directed behaviors.

The primary issue this paper will address is whether these unexplained decreases merely arise from unrecognized increases (i.e., activation in the jargon of functional brain imaging) present only in the "control state." Thus, on this argument, any control state, no matter how carefully it is selected, is just another task state with its own unique areas of activation. Unfortunately, in most instances there is insufficient information about the control state to judge whether the observed decrease arose in this manner.

We believe conceptual progress has suffered because of our inability to exclude explanations of the above type for regional decreases in brain activity and, more generally, to understand whether a specific level of activity in a given area of the brain can be considered its baseline. At the heart of the problem is the lack of agreed-upon characteristics defining a baseline state. In response to this dilemma we began with a generally accepted, quantitative circulatory and metabolic definition of brain activation (see *Background*, below). From this definition we specified criteria for a baseline state (i.e., the absence of activation by this definition). In so doing, we were able to determine that areas consistently exhibiting decreases in activity during specific goal-directed behaviors (3) did so from this baseline state. We believe these findings are consistent with our idea of a baseline or default state of the brain, the functions of which are revealed by those areas whose activities are suspended during many transient, attention-demanding, goal-directed activities.

Background

Although the human brain accounts for only about 2% of the body weight, it consumes nearly 20% of the oxygen we extract from the air we breathe. This dependence of the brain on oxygen is highlighted by the fact that failure of oxygen delivery to the brain, usually the result of a stoppage of the heart, results in unconsciousness within seconds. An examination of the relationship between oxygen delivery to the brain and flowing blood regionally within the brain (Fig. 2) highlights the nature of this dependency.

The signal used by PET to map changes in neural activity in the human brain is based on local changes in blood flow (1). Increased neural activity in a local brain region increases blood flow in that region. Scientists have known of this robust relationship for well over 100 years through repeated demonstrations in laboratory animals and humans (1). It was thought to reflect the changing needs of the brain for oxygen during changing mental activity.

Surprisingly, more recently it has been appreciated that these changes in blood flow are accompanied by smaller changes in oxygen consumption (4). This leads to a decrease in the amount of oxygen extracted from blood when blood flow increases and an increase in the amount of oxygen extracted when blood flow decreases. Thus, changes in blood flow accompanying local changes in brain activity are associated with significantly smaller changes in the amount of oxygen used by the brain (1). As a result of these relationships the local blood oxygen content parallels the change in brain activity because the amount of oxygen supplied changes more than the demand (Fig. 3). At the present time we do not fully understand why the relationship between

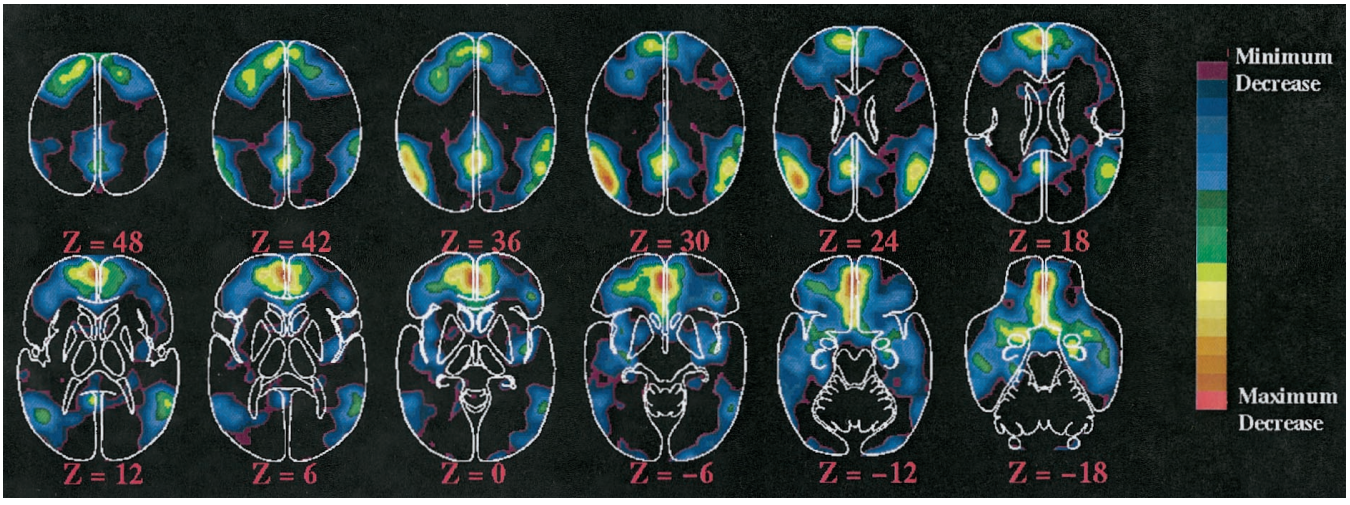

Fig. 1. Regions of the brain regularly observed to decrease their activity during attention demanding cognitive tasks. These data represent a metaanalysis of nine functional brain imaging studies performed with PET and analyzed by Shulman and colleagues (49). In each of the studies included, the subjects processed a particular visual image in the task state and viewed it passively in the control state. One hundred thirty-two individuals contributed to the data in these images. These decreases appear to be largely task independent. The images are oriented with the anterior at the top and the left side to the reader's left. The numbers beneath each image represent the millimeters above or below a transverse plane running through the anterior and posterior commissures (26).

oxygen delivery and oxygen consumption changes during changes in brain activity (see ref. 1 for a review), but this phenomenon has had great practical value for our ability to view changes in brain activity with fMRI.

Because fMRI signal intensity is sensitive to the amount of oxygen carried by hemoglobin (5–7), this change in blood oxygen content at the site of increased brain activity can be detected with fMRI. This phenomenon is the basis for fMRI (8, 9) and is usually referred to as the blood oxygen level-dependent (BOLD) signal, following Ogawa and colleagues (6).

The relationship of oxygen delivery to oxygen utilization can be measured quantitatively in the human brain with PET as the fraction of available oxygen (i.e., the arterial oxygen concentration) used by the brain. This measurement is usually referred to as the oxygen extraction fraction (OEF) (10–12). Researchers interested in blood flow and metabolic relationships in the brain have come to appreciate the spatial uniformity of the OEF measured in a resting state (e.g., lying quietly in a scanner with eyes closed but awake; see Fig. 4). This spatial uniformity exists despite considerable variation in resting oxygen consumption and blood flow within gray matter and an almost 4-fold difference between gray and white matter in both oxygen consumption and blood flow (Figs. 2 and 4). This relationship is altered in the normal brain only when areas briefly change their activity during specific behaviors (4, 13).

Heretofore the uniformity of the OEF at rest has not been considered in defining a baseline state of the human brain. Here we specifically propose to do so. The brain mean OEF was chosen as the baseline level of activity on the basis of its general uniformity in the eyes closed, resting state. This uniformity suggests that equilibrium has been reached between the local metabolic requirements necessary to sustain a long-term modal

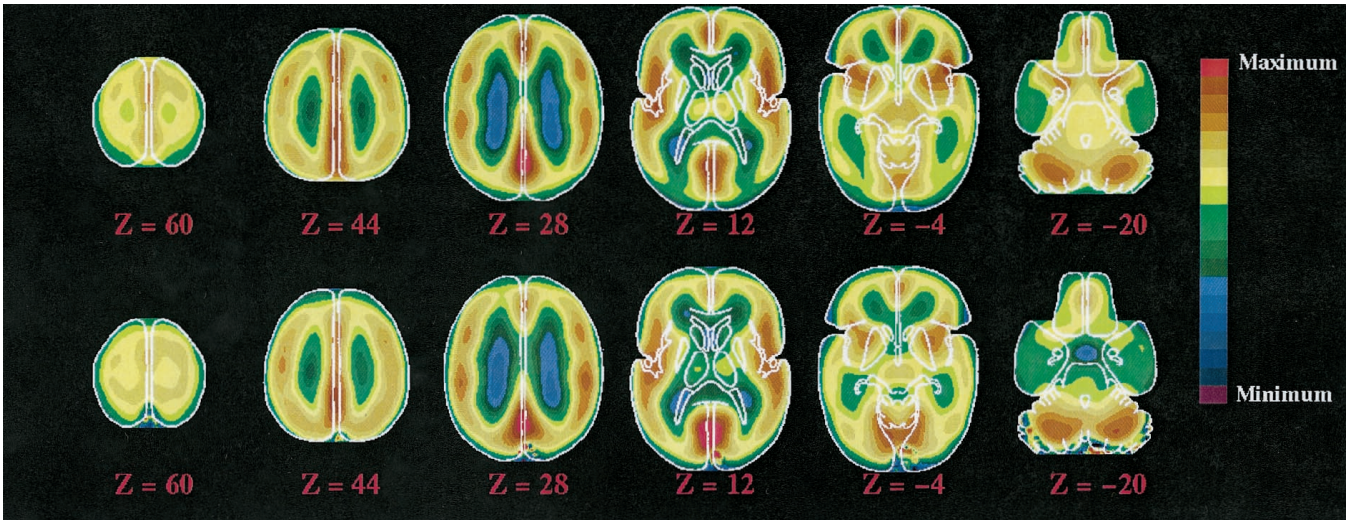

Fig. 2. Quantitative maps of blood flow (*Upper*) and oxygen consumption (*Lower*) in the subjects from group I while they rested quietly but awake with their eyes closed. The quantitative hemisphere mean values for these images are presented in Table 1. Note the large variation in blood flow and oxygen consumption across regions of the brain. These vary most widely between gray and white matter. Despite this variation, blood flow and oxygen consumption are closely matched, as also reflected in the image of the oxygen extraction fraction (i.e., the ratio of oxygen consumption to blood flow; see Fig. 4).

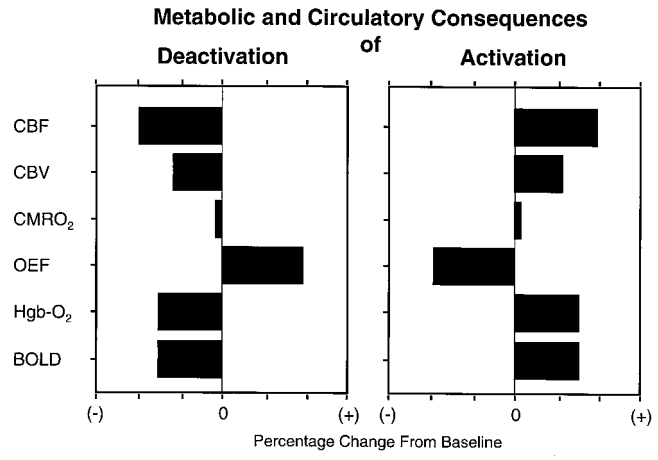

Fig. 3. A schematic representation of the metabolic and circulatory relationships occurring in areas of the brain with transient increases (Activation) or decreases (Deactivation) in the level of neural activity from a baseline or equilibrium state. Typically increases (*Right*) are characterized by increases in the cerebral blood flow (CBF) and the cerebral blood volume (CBV), with much smaller changes in the cerebral metabolic rate for oxygen ($CMRO_2$). As a result, there is a fall in the oxygen extraction fraction (OEF) and an increase in the amount of oxygen attached to hemoglobin exiting the brain (HbO_2). This latter change is responsible for the blood oxygen level–dependent (BOLD) signal used in functional magnetic resonance imaging (fMRI). Decreases from baseline (*Left*) are characterized as the opposite pattern of change.

level of neural activity and the level of blood flow in that region. We propose that this equilibrium state defines a baseline level of local neuronal activity. Consequently, those areas with a reduced OEF relative to the brain mean are defined as activated (i.e., neural activity is increased above the baseline level). Those areas not differing from the brain mean OEF are considered to be at baseline. In this scheme, increases in the OEF from the brain mean then define areas of deactivation (i.e., neural activity is decreased below the baseline level).

With these definitions in mind (Fig. 3) we used quantitative measurements of the OEF obtained with PET to examine those brain areas regularly observed to exhibit reductions in blood flow and blood oxygen level-dependent signal during goal-directed behaviors (3). Our reason for choosing these regions was to test the hypothesis that such decreases occur relative to a baseline state of brain activity (here defined as resting quietly but awake with eyes closed). In other words, decreases in brain activity do not have to be increases simply looked at from the opposite side of the equation. Rather, they are decreases from a true baseline or zero set point. If this hypothesis is correct, the chosen regions should exhibit an OEF similar to that of the rest of the brain in this baseline state. The OEF in these areas was measured in two independent groups of 19 normal adults resting quietly with eyes closed. These results were then extrapolated to a more complex control or baseline state (passive visual fixation) in a third group of 11 normal adults.

Methods

Subjects. Data from three subject groups were used for this analysis. The first two groups had served as control subjects in previously published studies from this laboratory (3, 14, 15). The third group was culled from previously unpublished data. All subjects were recruited from the Washington University community. None had any history of neurological or psychiatric illness. The Human Studies Committee and the Radioactive Drug Research Committee of Washington University approved all studies. Informed consent was obtained in accordance with their guidelines.

Group I consisted of 19 subjects (eight females) in whom quantitative CBF, CBV, OEF, and the $CMRO_2$ were measured while the subjects rested quietly but awake with eyes closed in a Siemens model 961 PET scanner (see below). Their ages ranged from 19 to 77 years, with a mean age of 43 years. Seventeen were right handed. They are described in greater detail elsewhere (15).

Group II consisted of 19 subjects (10 females) in whom quantitative CBF, CBV, OEF, and $CMRO_2$ were measured while the subjects rested quietly but awake with eyes closed in the PETT VI PET scanner (see below). Their ages ranged from 19 to 84 years, with a mean age of 42 years. Fourteen were right handed. They are described in greater detail elsewhere (14).

Group III (previously unpublished) consisted of 11 subjects

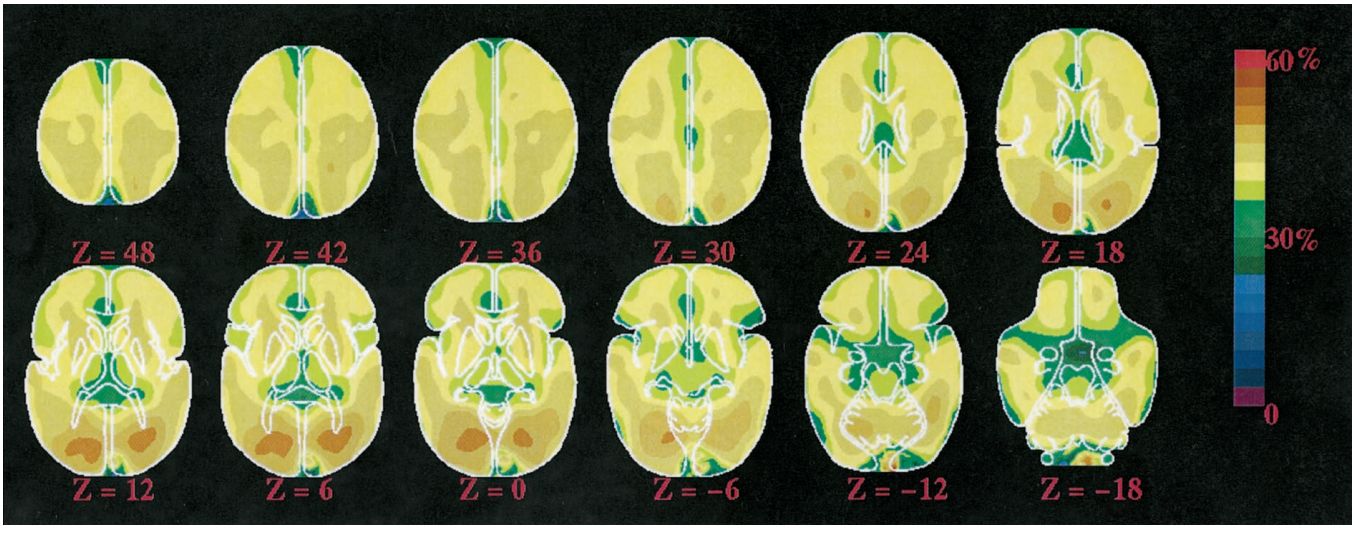

Fig. 4. Maps of the fraction of oxygen extracted by the brain from arterial blood (oxygen extraction fraction or OEF expressed as a percentage of the available oxygen delivered to the brain). The data come from 19 normal adults (group I, Table 1) resting quietly but awake with their eyes closed. The data were obtained with PET. Despite an almost 4-fold difference in blood flow and oxygen consumption between gray and white matter, the OEF is relatively uniform, emphasizing the close matching of blood flow and oxygen consumption in the resting, awake brain. Areas of increased OEF can be seen in the occipital regions bilaterally (see text for discussion).

The values for OEF, CBF, and $CMRO_2$ are expressed as local-to-global ratios (see *Methods*). For the 19 subjects in group I the global values for OEF and CBF (± SD) were 0.40 ± 0.09 (dimensionless) and 46 ± 8 ml/(min × 100 *g*), respectively. The mean arterial oxygen content for this group was 16.6 ± 0.16 ml/ml. From these data quantitative images of the $CMRO_2$ were created that yielded a mean cerebral hemisphere value of 2.94 ± 0.41 ml/(min × 100 *g*) or 1.31 ± 0.18 μmol/(min × *g*). The asterisks denote values that differ significantly from the global mean after correction for multiple comparisons.

(five females) in whom qualitative CBF was measured while the subjects rested quietly but awake with eyes closed and again while they passively viewed a visual fixation cross hair in the middle of a television monitor. Five such paired measurements were obtained. Their ages ranged from 19 to 40 years, with a mean age of 27 years. Eight subjects were right handed. There is no record of the handedness of the other three. The data for group III were also acquired with the PETT VI PET scanner (see below).

Imaging Methods. The subjects in group I were scanned with a Siemens model 961 scanner (Siemens Medical Systems, Hoffman Estates, IL) (16, 17). Images were reconstructed by using filtered back projection and scatter correction with a ramp filter at the Nyquist frequency. All images were then filtered with a three-dimensional Gaussian filter to a uniform resolution of 16-mm full width at half-maximum.

In the subjects in groups II and III, studies were performed on the PETT VI scanner (18, 19). The PETT VI system was used in the low-resolution mode. Images were then filtered with a three-dimensional Gaussian filter to a uniform resolution of 17-mm full width at half-maximum.

Quantitative regional OEF, CBF, and $CMRO_2$ were measured by using a combination of O^{15}-labeled radiopharmaceuticals as described (11, 12, 20–22). Qualitative CBF was measured in the subjects in group III. In this instance $H_2{}^{15}O$ images consisting of normalized PET counts were used to create maps of the distribution of blood flow in the brain (21, 23, 24).

Regions of Interest. The location of each region of interest analyzed in this study was obtained directly from the right hand side of table 1 of the study by Shulman and colleagues (3). These regions were chosen because they reliably predict the location of areas of the human brain exhibiting reductions in activity, as measured with either PET or fMRI, during the performance of a variety of cognitive tasks (3). Their coordinates are listed in Tables 1 and 2 of the present study. The regions are referred to by the Brodmann area originally assigned to them by Shulman *et al.* (3).

Furthermore, a center-of-mass algorithm (25) was used to search the OEF data sets for any significant deviations from the hemisphere mean outside of the specific areas chosen for analysis (preceding paragraph).

Data Analysis. A 12-mm sphere was centered on the stereotaxic coordinates of each region of interest (see Tables 1 and 2) for each subject's individual images of CBF, OEF, and $CMRO_2$. Each regional value was divided by the subject's mean global

Table 2. Data obtained from subjects in group II while they rested quietly but awake with their eyes closed

The values for OEF, CBF, and $CMRO_2$ are expressed as local-to-global ratios (see *Methods*). For the 19 subjects in group II the global values for OEF and CBF (± SD) were 0.30 ± 0.09 (dimensionless) and 48 ± 10 ml/(min × 100 *g*), respectively. The mean arterial oxygen content for this group was 17.0 ± 0.02 ml/ml. From these data quantitative images of the $CMRO_2$ were created that yielded a mean cerebral hemisphere value of 2.17 ± 0.41 ml/(min × 100 *g*) or 0.97 ± 0.17 μmol/(min × *g*). The asterisks denote values that differ significantly from the global mean after correction for multiple comparisons.

Table 3. Areas with maximum absolute deviation of the OEF from the hemisphere mean in subjects from group I

Brodmann area	*x*	*y*	*z*	OEF	*P*
11	8	33	−22	1.491	0.0007
19	−23	−79	6	1.217	<0.0001
19	29	−67	4	1.201	<0.0001
18	−29	−93	12	1.194	0.001
18	23	−79	18	1.182	0.0002
18	23	−81	10	1.181	<0.0001
37	33	−51	−8	1.138	0.0005
31	23	−47	40	1.121	<0.0001
31	17	−33	50	1.103	0.0003
19	21	−83	30	1.098	0.08

Note that these are all increases in the OEF signifying areas of deactivation in the baseline state of resting but awake with eyes closed. With the exception of Brodmann area 11 located in the right gyrus rectus, these areas cluster in visual areas of the occipital and parietal cortices. The conventions used are similar to those of Tables 1 and 2.

value for that image, creating a local to global ratio for that region. A two-tailed, one-sample Student's *t* test was performed to determine whether this ratio differed from a predicted value of 1. The level of significance was adjusted for multiple comparisons.

Results

Regional as well as whole-brain measurement values of CBF, OEF, and $CMRO_2$ for groups I and II are presented in Tables 1 and 2. None of the areas selected for study (3) exhibited an OEF significantly different from the hemispheric mean (compare Figs. 1 and 4). The correlation between the regional values of OEF obtained independently on the two groups was excellent ($r = 0.89$). By our definition (see *Background*), therefore, none of these areas was activated in subjects who were awake but resting quietly with their eyes closed (two independent groups of 19 subjects each).

To complete our analysis, the data sets from groups I and II were automatically searched (25) for any deviations in the OEF above or below the hemisphere mean. No significant decreases in OEF were found signifying areas of activation. In arriving at this determination we had to exclude several "areas" falling in high-noise areas at the edge of the brain or, in some instances, clearly outside of the brain. However, we did find, bilaterally, areas within extrastriate visual cortices that exhibited a significantly increased OEF from the hemisphere mean. These changes are readily apparent in Fig. 4, and their locations are given in Tables 3 and 4. By our definition these apparent visual areas are deactivated when subjects are awake but resting quietly with their eyes closed.

Table 4. Areas with maximum absolute deviation of the OEF from the hemisphere mean in subjects from group II

Brodmann area	*x*	*y*	*z*	OEF	*P*

7	17	−63	46	1.073	0.02

Note that these are all increases in the OEF signifying areas of deactivation in the baseline state of resting but awake with eyes closed. These areas cluster in visual areas of occipital and parietal cortices. The conventions used are similar to those of Tables 1 and 2.

Although none of the areas selected for study appear to be activated by our definition, two areas in both groups (i.e., M31/7 and M10) have both resting CBF and $CMRO_2$ significantly above the global mean (criteria: $P < 0.0038$ for both measurements in both groups). Likewise, two additional areas in both groups (i.e., L39/19 and L9) have both resting CBF and $CMRO_2$ significantly below the global mean.

Resting quietly awake with the eyes closed is much less frequently used as a control state in functional imaging studies than visual fixation of a cross hair on a television monitor or passive viewing of a stimulus. The data presented in Tables 1 and 2 as well as Figs. 1 and 4 do not tell us whether areas exhibiting significant reductions in activity during active task performance (3) become more active in the control states of visual fixation than when the eyes are closed. If this were to occur, reduced activity seen in the task state could simply reflect the absence of this increase in activity during fixation and passive viewing.

The data from group III resolved this issue. No significant change in blood flow was found for any of the regions listed in Tables 1 and 2 when subjects went from the eyes closed and awake but resting state to passively viewing a fixation cross hair in the middle of a television monitor. Furthermore, it should be noted that those areas of extrastriate visual cortex exhibiting deactivation in the eyes closed state (Fig. 4) increase their BF when the eyes are opened (details to be published separately). This observation is consistent with the hypothesis that the baseline state of these areas is more nearly approximated when subjects rest quietly with their eyes open.

Discussion

Our study represents a comprehensive analysis of the uniformity of the OEF in the normal human brain while adult subjects are awake and resting quietly with their eyes closed. These data affirm the long-held impression of a relatively consistent relationship between oxygen delivery and oxygen consumption in the human brain (Fig. 2). Obvious decreases in the OEF from the brain mean, reflecting areas of activation (1), are not apparent in our data when subjects rest quietly with their eyes closed or open.

Areas of deactivation (i.e., increased OEF), primarily in extrastriate visual areas, were clearly apparent from our data (Fig. 4 and Tables 3 and 4). It is of interest to note that these same increases in OEF were also noted in some of the earliest PET work on normal humans (27), although their possible significance was not appreciated. Their presence suggests that the baseline state for these areas may well be associated with the eyes being open. This hypothesis receives support from our comparison of eyes closed versus passive visual fixation, in which we noted an increase in the blood flow in these areas as subjects opened their eyes. Further work remains, including actual measurements of OEF in these areas in the eyes open and closed states. Nevertheless, these data are consistent with our hypothesis that the baseline state of these areas is more nearly approximated when the eyes are open.

More generally our data are consistent with the hypothesis that the brain mean OEF defines a baseline level of neuronal activity. The uniformity of the OEF in the absence of specific goal-directed activities supports our belief that an established equilibrium exists between the local metabolic requirements necessary to sustain a long-term modal level of neural activity and the level of blood flow in a particular region. Deviations from this equilibrium produced by transient changes in this modal level of neural activity manifest themselves as changes in the OEF and provide us with the signals underlying modern functional brain imaging with fMRI.

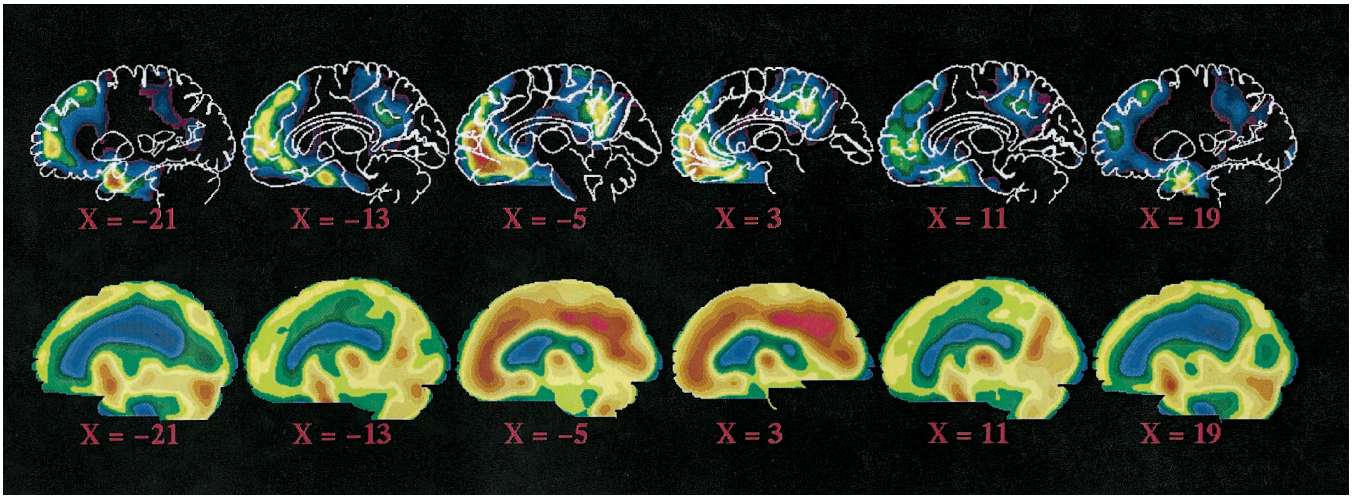

Fig. 5. Regions of the brain regularly observed to decrease their activity during attention-demanding cognitive tasks shown in sagittal projection (*Upper*) as compared with the blood flow of the brain while the subject rests quietly but is awake with eyes closed (*Lower*). The data in the top row are the same as those shown in Fig. 1, except in the sagittal projection, to emphasize the changes along the midline of the hemispheres. The data in the bottom row represent the blood flow of the brain and are the same data shown in horizontal projection in the top row of Fig. 2. The numbers below the images refer to the millimeters to the right (positive) or left (negative) of the midline.

Areas consistently observed to decrease their activity in a variety of goal-directed, cognitive activation paradigms (Fig. 1) do not exhibit a reduced OEF (i.e., evidence of activation) in this typical resting state (Tables 1 and 2). While a null result such as this (i.e., the regional OEF does not differ from the hemisphere mean) might be received with some caution, the relatively tight 95% confidence limits for the measurement of OEF (±3%, based on an analysis of the group I data) make it very unlikely that significant reductions in OEF, of even lesser magnitude than the increases seen in the visual system (Fig. 4 and Tables 3 and 4), would have been missed. Thus, we believe our findings indicate that these localized decreases in activity (Figs. 1 and 5) (3) occur as decreases from a baseline level of activity rather than the return to baseline of an area of unsuspected activation.

The presence of a consistent set of decreases in activity within a select set of brain areas strikingly independent of the goal-directed behaviors with which they are associated suggests to us that specific brain functions unique to the baseline state itself are being temporarily suspended. We posit that areas decreasing their activity in this manner may be tonically active in the baseline state, as distinguished from areas that are transiently activated in support of varying goal-directed activities. Understanding the exact functions served by such tonically active areas would require much additional work, yet some indication of the directions this research might profitably take is revealed by our current knowledge about two of them. These are midline areas within the posterior cingulate and precuneus and within the medial prefrontal cortex (MPFC) (see Fig. 5).

The response of posterior cingulate and precuneus neurons to visual stimuli, for example, crucially depends on the physical characteristics of the stimulus (for a recent review see ref. 28). Small spots of light to which a monkey may be attending and responding do not elicit neuronal responses in this area. In contrast, large, brightly textured stimuli elicit responses, even if they are totally irrelevant to tasks the animal is performing. These observations are consistent with the fact that elements of the dorsal stream of extrastriate visual cortex [area M in the owl monkey (29) and area PO in the macaque (30)] are part of a network of areas concerned with the representation of the visual periphery.

Severe damage to the parietal cortex, when it extends medially to include the precuneus and the posterior cingulate, produces a condition known as Balint's syndrome (31), the cardinal feature of which is the inability to perceive the visual field as a whole (i.e., a fixed form of tunnel vision usually referred to as simultanagnosia), despite intact visual fields, during simple confrontation with single small stimuli. Furthermore, patients with Alzheimer's disease show early reductions of metabolic activity in this area (32) and have been reported to show abnormalities in the processing of extrafoveal information (33).

Thus, the posterior cingulate cortex and adjacent precuneus can be posited as a tonically active region of the brain that may continuously gather information about the world around, and possibly within, us. It would appear to be a default activity of the brain with rather obvious evolutionary significance. Detection of predators, for example, should not, in the first instance, require the intentional allocation of attentional resources. These resources should be allocated automatically and be continuously available. Only when successful task performance demands focused attention should such a broad information gathering activity be curtailed. The central importance of such a function is underscored by the observation that restoration of consciousness from a vegetative state (or at least external awareness, as it can be assessed at the patient's bedside) is primarily heralded by a restoration of metabolism in parietal areas, including the precuneus (34).

Finally, we note the selective vulnerability of the posterior cingulate and precuneus in such conditions as carbon monoxide poisoning [i.e., acute hypoxia (34)], diffuse brain ischemia (35), and Alzheimer's disease (32). This vulnerability, in the case of hypoxia and ischemia, has been ascribed to the position of the posterior cingulate and precuneus in the border zone between two of the main arteries supplying blood to the brain. We wonder whether the exceptionally high metabolic rate exhibited by the posterior cingulate and precuneus adds to their vulnerability (Tables 1 and 2 and Fig. 5). This hypothesis receives some support from animal models of schizophrenia (36), based on pharmacologically induced, excitatory amino acid toxicity that preferentially (but without explanation to date) targets this area.

Another midline area of the cortex exhibiting prominent decreases in activity during focused attention is MPFC (Figs. 1 and 5). Because of the large body of data implicating, in particular, the ventral aspects of this area of the brain and its connections in emotional processing within the brain, it has been

posited that decreases during focused attention reflect a dynamic interplay between ongoing cognitive processes and the emotional state of the subject (37–40), a hypothesis we explore in more detail in our accompanying papers (41, 42). More specifically, it has been proposed that in humans the MPFC may play a role in the integration of emotional and cognitive processes by incorporating emotional biasing signals or markers into decision-making processes (43).

Anatomically, the ventral MPFC is composed of a number of cytoarchitectonically discrete areas that receive a wide range of sensory information from the body and the external environment (44–46) and are heavily interconnected with limbic structures such as the amygdala, ventral striatum, hypothalamus, midbrain periaquaductal gray region, and brainstem autonomic nuclei (44, 45). Electrophysiological studies in monkeys indicate that orbital and medial prefrontal neurons respond to stimuli based on their reward and nonreward associations (for a review see ref. 47).

Thus, as we come to associate general monitoring of sensory information with the posterior cingulate and adjacent precuneus, we may also come to associate an evaluation of the salience of this information with medial and orbital frontal cortices. We posit that when an individual is awake and alert and yet not actively engaged in an attention-demanding task, a default state of brain activity exists that involves, among other areas, the MPFC and the posterior cingulate and precuneus. Information broadly arising in the external and internal milieu is gathered and evaluated. When focused attention is required, particularly if this activity is novel, activity within these areas may be attenuated. This attenuation in activity reflects a necessary reduction in resources devoted to general information gathering and evaluation. The MPFC with the posterior cingulate and medial parietal cortices may well be the "sentinels" to which William James referred (see ref. 48, p. 73), which, "when beams of light move over them, cry 'who goes there' and call the fovea to the spot. Most parts of the skin do but perform the same office for the fingertips."

More generally, an appreciation of the important activities that may underlie the baseline state of the human brain will certainly enrich our understanding of its function. Strong hints about the direction research in this area might take come, we believe, from the heretofore mysterious activity reductions routinely seen by modern functional brain imaging techniques during the performance of goal-directed behaviors. In addition to the midline areas we have discussed, it is necessary to consider as well the role(s) of more lateral cortical areas (especially prominent in parietal cortex), which also appear as elements of this default system.

Abstract

Disgust has been implicated as a potential causal agent underlying socio-political attitudes and behaviors. Several recent studies have suggested that pathogen disgust may be a causal mechanism underlying social conservatism. However, the specificity of this effect is still in question. The present study tested the effects of disgust on a range of policy preferences to clarify whether disgust is generally implicated in political conservatism across public policy attitudes or is uniquely related to specific content domains. Self-reported socio-political attitudes were compared between participants in two experimental conditions: 1) an odorless control condition, and 2) a disgusting odor condition. In keeping with previous research, the present study showed that exposure to a disgusting odor increased endorsement of socially conservative attitudes related to sexuality. In particular, there was a strong and consistent link between induced disgust and less support for gay marriage.

Introduction

Disgust is increasingly seen as playing an important role in the formation and maintenance of political and social attitudes [1]. Disgust sensitivity and reactivity have been shown to relate to political conservatism generally [2,3,3–7] and have been implicated in negative and hostile attitudes towards a range of social out-groups, particularly homosexuals [2,6–10]. In keeping with the aforementioned research, some have suggested that disgust is specifically related to conservative attitudes that pertain to social or moral purity [11], and, in particular, sexual purity [4,12,13]. One potential reason for these relations is that disgust plays an adaptive role in preserving individuals from the threat of infectious disease [14,15].

It has been posited that the Behavioral Immune System, which uses the physiological response of disgust as its first line of behavioral defense, shapes political attitudes and resultant policy preferences [5,16]. As stated by Terrizzi, Shook and McDaniel in their meta-analysis "(A)cross 24 studies, the findings suggest that there is a moderate, positive relationship between behavioral immune system strength and social conservatism" [7]. Despite connections being made between disgust and political ideology, additional work is needed to clarify if disgust sensitivity and/or disgust reactivity are associated with political ideology and what domains of political ideology are related to disgust. Smith and colleagues [2] recently addressed these questions by investigating the relations between disgust sensitivity, disgust reactivity – meaning *in vivo* physiological reaction to disgusting stimuli – and responses to a range of specific political issue items using the well-known Wilson-Patterson scale [17]. Heightened disgust sensitivity and reactivity were both negatively related to attitudes towards gay marriage and premarital sex but not significantly related to a range of other political issues (e.g., gun rights, school prayer, immigration). They also showed that, after controlling for demographic and experimental factors, greater disgust sensitivity was associated with less support for abortion. Said otherwise, this study showed that both trait and state disgust predicted less support for gay marriage and premarital sex and trait disgust predicted less support for abortion. It is noteworthy that, contrary to their predictions, Smith and colleagues failed to show any significant relation between state or trait disgust and attitudes about pornography. This is, however, not too surprising given the limited body of research showing a link between disgust and attitudes about pornography [18].

Evidence from Smith et al. [2] and similar research [9] is compelling but causal interpretations are not possible given their utilization of correlational designs. This limitation was rectified by Inbar and colleagues [3] who experimentally tested the effects of odor induced disgust on self-reported warmth toward homosexuals. They found that, relative to participants in a no odor control condition, participants in the disgust odorant condition reported less warmth toward homosexuals. These findings are similar to those reported by Terrizzi and colleagues [6], who showed that the induction of disgust caused conservative participants to report a decreased willingness to come into contact with homosexuals. What remains to be seen is if the experimental induction of disgust causes attitudinal shifts for other issues related to sexual purity

(e.g., premarital sex, abortion, etc.) and if induced disgust causes changes in attitudes towards public policies related to gay marriage.

In the present study we extend previous research by carrying out a true experiment to test the role of induced disgust on the same socio-political attitudes measured by Smith and colleagues. This allows us to test the causal role of disgust on a variety of public policy stances while still focusing on issues of sexual purity, particularly gay marriage. Core/contamination disgust was induced via noxious odorant, which is a primal approach closely reflecting the evolutionary adaptation of this emotion [19]. Moreover, manipulating physical disgust via smell allowed for a continuous induction of the emotion, rather than a brief priming of the emotion prior to measurement. In keeping with the findings of Smith and colleagues [2], we expected the foul disgust odorant, in this case butyric acid, which smells like vomit, to robustly engage the emotion of disgust and decrease approval of gay marriage. Smith and colleagues [2] reported weak effects between state disgust and attitudes about premarital sex and also found non significant relations between state disgust and attitudes about abortion or pornography. Similarly, both Smith and colleagues [2] and Inbar and colleagues [9] reported weak, albeit significant, relations between disgust sensitivity and attitudes about abortion. We therefore expected weak, or perhaps non-significant, effects of our experimental manipulation on attitudes about premarital sex, pornography, and abortion.

Methods

Procedures

All procedures were approved by the University of Arkansas Institutional Review Board. All participants provided written informed consent prior to participating in any experimental procedures. Data for the present study can be found at http://dx.doi.org/10.6084/m9.figshare.930730. Community members and students were recruited via an online advertisement and compensated $10 for their time. All procedures were completed in a small group format ($n = 4$–8). Following informed consent, participants were then escorted into a small room (10′x10′x17.5′) with individual desks. An experimenter operated a timed slideshow that displayed experimental instructions while monitoring participants at the back of the room, out of their sight. Participants were assigned to either a disgust odor condition or a control (no odor) condition. Ten minutes prior to participant arrival, an experimenter placed four drops of 99% butyric acid [20,21] on two small cotton pads and hid these pads at the front and back of the room. Pads were replaced and the room aerated between experimental groups. Immediately upon entering the experimental room, all participants completed disgust ratings and socio-political opinion questions. The Three Domains of Disgust Scale (TDDS), Conservative Liberal Scale, and demographics were completed in a separate, odor-neutral corridor (measures are listed in order of administration below). The disgust induction was not, therefore, expected to have any effect on the TDDS or Conservative Liberal Scale scores.

Participants

Smith and colleagues reported medium ($r = .37$) to large ($r = .45$) relations between disgust reactivity (state disgust) and attitudes about gay marriage [2]. Power analyses were conducted using G*Power [22]. Results suggest that, given alpha of .05 and power of .80, a sample of 33 total participants would be required to detect an effect size of .45, and a sample of 54 total participants would be required to detect an effect size of .37. Smith and colleagues reported small relations ($rs = .10$ to .28) between disgust reactivity and attitudes about other issues of sexual purity (e.g., premarital sex, pornography, abortion). Given an alpha of .05 and power of .80, a sample of 779 total participants would be required to detect an effect size of .10 and a sample of 95 total participants would be required to detect an effect size of .28. A total of 57 participants were included in the present study, thirty of whom were randomly allotted to the control group. As such, the present sample size is only sufficiently powered for medium to large effects.

A majority of participants were Caucasian/white ($n = 51$), self-described Christian ($n = 40$), and heterosexual ($n = 53$); there were no significant differences between the two experimental groups on any of the aforementioned demographic variables. There was a significant difference in gender distribution between the two experimental groups, X^2 (1) $= 6.22$, $p = .01$, with relatively more female than male participants in the control group ($n = 21$ and 9, respectively) compared to the disgust odor group ($n = 10$ and 17, respectively). The average age of the sample was 32.37 ($SD = 14.15$). The control group ($M = 35.33$, $SD = 15.59$) was marginally older than the disgust odor group ($M = 29.07$, $SD = 11.79$), F (1, 55) $= 2.87$, $p = .10$.

Measures

Disgust ratings. As a manipulation check, participants were asked to select a number ranging from 0 'Not at all' to 8 'Very much so' to indicate the degree to which they currently felt "disgusted, nauseated, repulsed."

Socio-political opinion questions. The Wilson-Patterson short-response format [17], which asks participants if they agree, disagree, or are uncertain on a range of currently salient public policy issues, was used to measure socio-political attitudes. Responses were recoded so that 1 = agree, 2 = uncertain, and 3 = disagree. Participants responded to 16 items concerning social, economic, regulatory, and international public policy. Even though our predictions were only concerned with sex-related attitudes, we opted to include other Wilson-Patterson items to allow for a direct comparison between our findings and those published by Smith and colleagues [2]. Eight items were worded such that higher scores reflected more agreement with conservative attitudes and eight items were worded such that lower scores reflected less agreement with conservative attitudes (see Table 1). Participants also completed four 5-point items that were specifically concerned with same sex marriage. The first of the aforementioned items was scaled from 1 'strongly oppose' to 5 'strongly favor' and was the same item used by Smith and colleagues [2] while the latter three items, which were developed for the present study, were scaled from 1 'strongly agree' to 5 'strongly disagree' (Table 1).

Conservatism Liberal Scale. The Conservatism Liberal Scale [23] is a one-item measure presenting the following: "We hear a lot of talk these days about liberals and conservatives. Here is a 7-point scale on which the political views that people might hold are arranged from extremely liberal to extremely conservative." Participants are then asked to place themselves on the scale from 1 (extremely conservative) to 7 (extremely liberal).

Three Domains of Disgust Scale. The TDDS [13] is a 21-item self-report scale that measures three distinct domains of disgust sensitivity (moral, sexual, and pathogen). Each factor is represented by seven items measured on a zero to 6-point scale, ranging from 'not at all disgusting' to 'extremely disgusting'. The TDDS has strong psychometric properties [24] and internal consistencies of the TDDS factors were moderate within the present sample, ($\alpha_{\text{Moral Disgust}} = 0.83$), ($\alpha_{\text{Sexual Disgust}} = 0.82$), and ($\alpha_{\text{Pathogen Disgust}} = 0.79$).

Table 1. Descriptive data and summary of ANOVAs split by experimental groups.

Dependent variables	Condition	Mean (SD)	With Covariates *F* (ηp^2)	Without Covariates *F* (ηp^2)
5-Pt. Gay Marriage Items				
The federal government should support a constitutional amendment banning gay marriages*	Control	1.57 (1.04)	7.80 (.13)[b]	4.36 (.07)[a]
	Odor	2.33 (1.69)

	Odor	1.48 (.58)		

Note. All ANCOVA $df = 1, 52$ and ANOVA $df = 1, 56$. "*" denotes items for which agreement (i.e., lower score) are consistent with a more conservative stance. Covariates included for ANCOVA analyses were gender, age, and moral disgust propensity.
Superscript "[a]" denotes $p \leq .05$, superscript "[b]" denotes $p \leq .01$, superscript "[c]" denoted $p \leq .001$.
doi:10.1371/journal.pone.0095572.t001

Results

A series of analysis of variance (ANOVA) tested dispositional differences between experimental groups on political ideology (conservative-liberal) and moral, sexual, and pathogen sensitivities. Results revealed that the no odor control group endorsed significantly more moral disgust sensitivity ($M = 31.14$, $SD = 5.90$) than the disgust odor group, ($M = 27.30$, $SD = 8.23$), $F(1, 55) = 4.16$, $p = .05$. The two experimental groups did not differ in terms of political ideology, sexual disgust, or pathogen disgust, (all $ps > .10$). The TDDS was completed several minutes after the disgust induction and in a corridor that was separate from the disgust odor infused room. If the disgust induction did have a lingering effect on TDDS scores, then participants would have likely also scored higher on the pathogen disgust subscale, which was not the case. It is, therefore, unlikely that the between group difference in moral disgust was due to the disgust induction.

An analysis of variance (ANOVA) showed that participants in the disgust odor condition reported more subjective disgust during the manipulation check ($M = 3.85$, $SD = 2.03$) than participants in the control condition ($M = 0.37$, $SD = 1.03$), $F(1, 52) = 68.56$, $p < .01$, $d = 2.16$. This effect remained significant after adding gender, age, and moral disgust sensitivity as covariates (see Participants section and the previous paragraph), $F(1, 52) = 48.28$ $p < .01$.

To account for between group differences in demographic and dispositional variables, a series of ANCOVAs – with gender, age, and moral disgust sensitivity as covariates – were carried out with the 4 sexual purity Wilson-Patterson and four 5-point gay marriage items. False discovery rates were controlled for using adaptive alpha correction procedures outlined by Benjamini and Hoochberg [25]. As expected, attitudes about gay marriage were affected by the disgust induction, with participants in the disgust odor condition reporting less agreement with gay marriage (as measured by the one Wilson-Patterson item and three 5-point items) and less opposition (and more support) to a constitutional ban on gay marriage ($ps < .01$). Also consistent with our predictions and the findings of Smith et al. [2], we found that participants in the disgust odor condition disagreed significantly more with the Wilson-Patterson premarital sex ($p \leq .01$) item. Consistent with our own prediction but in contrast with the findings of Smith and colleagues [2], participants in the disgust odor condition reported more disagreement with pornography ($p \leq .01$). While participants in the disgust odor condition did report less agreement with abortion rights, this effect was not significant ($p = .23$). Exploratory analyses revealed that participants in the disgust odor condition were in significantly more agreement with Biblical truth ($p < .001$). The experimental groups did not significantly differ on any of the remaining Wilson-Patterson items (all $ps > .05$). See Table 1 for a summary.

Group differences on all items were also analyzed with a series of ANOVAs. Consistent with ANCOVA results, univariate ANOVAs showed that participants in the disgust odor condition reported significantly less support for allowing individuals to marry whomever they wish ($p = .009$) and for allowing friends or family members to pursue same sex marriages ($p = .003$). Participants in the disgust odor condition also reported less agreement with the Wilson-Patterson gay marriage item ($p = .034$), less agreement with nationwide legalization of same-sex marriage ($p = .023$), and less opposition to an amendment banning gay marriage ($p = .041$); however, these effects were not significant after alpha correction. While participants in the disgust odor condition reported less agreement with premarital sex, pornography, and abortion, these effects were not statistically significant (all $ps > .05$). Consistent with ANCOVA results, univariate analyses showed that participants in the disgust odor condition reported more support for the Biblical truth item ($p = .017$). Scores on the remaining Wilson-Patterson items did not significantly differ between the two experimental groups (all $ps > .10$). See Table 1 for details.

Given that several effects were enhanced by the inclusion of covariates, correlations between age, moral disgust, and items measuring attitudes about sexual purity were inspected. There were strong correlations between age and several other variables, with older participants reporting more moral disgust sensitivity ($r = .43$, $p \leq .01$), less agreement with legalizing gay marriage ($r = .35$, $p \leq .01$), and less agreement with the Wilson-Patterson gay marriage item ($r = .34$, $p \leq .05$). Similarly, participants who reported more moral disgust sensitivity also reported more conservative attitudes for all items related to gay marriage ($rs \leq .30$ and $ps \leq .05$). A series of ANOVAs also revealed that female participants disagreed more with pornography compared with male participants. A two-way ANOVA with gender and experimental condition as the IVs and attitudes about pornography as the DV failed to show a significant gender by condition interaction $F(1, 53) = 0.83$, $p = .37$. None of the covariates were significantly related to attitudes about premarital sex ($ps > .05$). Taken as a whole, inspection of the relations between covariates and the dependent variables suggests that gender only affected attitudes about pornography, age and moral disgust sensitivity affected attitudes related to gay marriage, and no covariates were significantly related to attitudes about premarital sex.

Visual inspection of the distribution of the friend of family member same-sex marriage item – which demonstrated the largest effect size ($d = .82$) – suggested that the disgust odor induction caused attitudes to literally shift to the right (Figure 1). A smaller percentage of participants in the disgust odor condition strongly agreed with allowing friends or family members to pursue same-sex marriage and a larger percentage in this group strongly disagreed with such an idea. For example, zero participants in the no odor control group compared to 25.9% of participants in the disgust odor group strongly disagreed with allowing friends or family to pursue same-sex marriage. Interestingly, the experimental manipulation did not appear to dramatically affect the percentage of participants who endorsed more moderate attitudes (i.e., somewhat oppose to somewhat favor).

Discussion

Disgust has an important, causal relationship with political attitudes concerning sexual conduct. In an experiment manipulating odor-based disgust, participants exposed to the smell of butyric acid reported increased subjective disgust and more politically conservative attitudes concerning gay marriage, premarital sex, pornography, and Biblical truth. Rejection of gay marriage was a particularly strong response to the disgust-inducing odor, perhaps because of the connection between homosexuality and perceptions of sexual impurity [4,26]. The finding that belief in Biblical truth was greater among participants in the disgust odor condition was unexpected but is nonetheless consistent with previous work showing a relation between disgust and scrupulosity or being careful to avoid doing wrong. Indeed, Olatunji presented data that suggested a causal chain between disgust, scrupulosity, and conservative beliefs about homosexuality [10]. Future research should continue testing the causal effects of disgust on religious beliefs and the effects of religion on sexual attitudes.

We report non-significant findings for a variety of non-sexual socio-political attitudes (e.g., tax cuts, illegal immigration, etc.), but we do not interpret these null findings as evidencing an absence of relations between disgust and non-sexual socio-political attitudes.

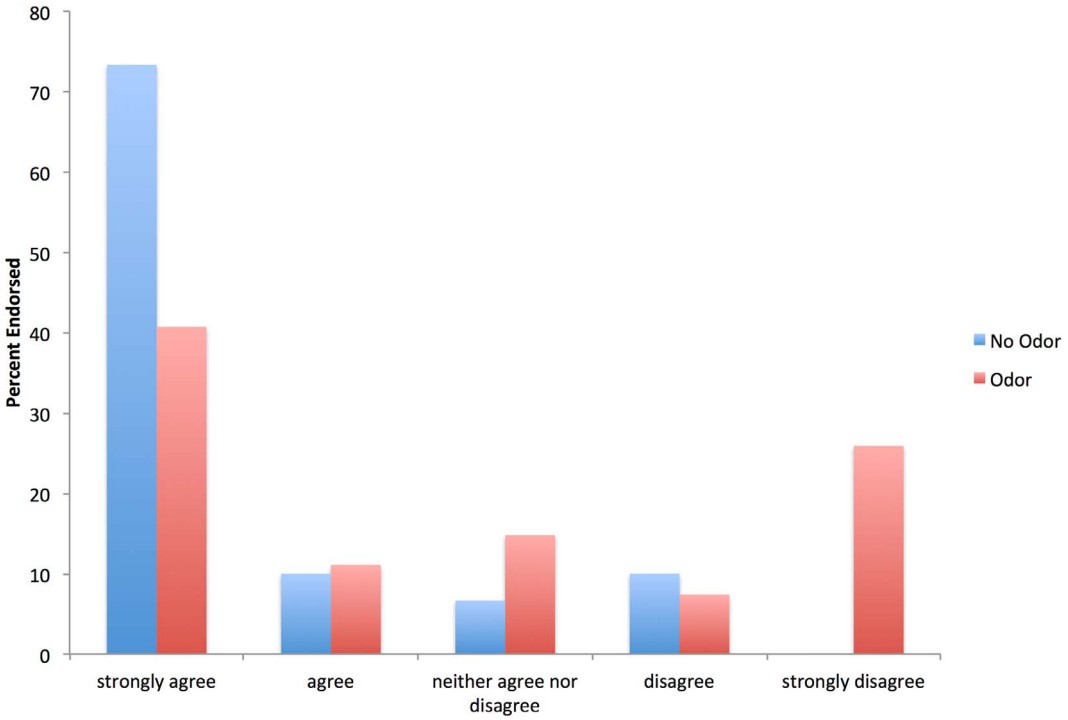

Figure 1. Attitudes about the following statement: "If a close friend of family member were gay, I would support their right to having a same-sex marriage."
doi:10.1371/journal.pone.0095572.g001

Replication with larger samples is needed before unconditional conclusions can be drawn, particularly with regard to smaller effects, which the present study was not appropriately powered to detect [e.g., abortion (see Participants section)]. Nonetheless, the present findings suggest that odor-induced disgust had a stronger effect on sexual attitudes than non-sexual attitudes (save for Biblical truth). The effects of disgust on sex-related attitudes, particularly those concerning gay marriage, are especially convincing when the present results are considered in the context of previous research [2,4,9]. For example, Smith and colleagues [2] reported very similar findings: greater changes in skin conductance following disgust provocation predicted stronger conservative views on gay marriage and premarital sex. However, the experimental approach of our study advances causal claims, particularly with regard to the effects of state disgust on views related to individual liberties pertaining to sexual orientation.

Participants in the no odor control condition were older, endorsed more moral disgust sensitivity, and were comprised of more females when compared to participants in the disgust odor condition. Gender was related to decreased agreement with pornography while age and moral disgust sensitivity were related to decreased agreement and support for same-sex marriage. It is, therefore, understandable that the inclusion of age, gender, and moral disgust sensitivity as covariates enhanced the magnitude of the experimental effect on attitudes about pornography and gay marriage. These results also suggest that extra emphasis should be placed on most of the ANCOVA results relative to the univariate analyses. Given the absence of relations between any of the covariates and premarital sex, it is difficult to determine precisely why the addition of covariates boosted this specific effect. The simplest explanation is that the addition of covariates reduced residual variance enough to push up effect size estimates and push down alpha estimates below significance thresholds. Regardless, the present findings, particularly those that were only significant with covariates (i.e., attitudes about premarital sex and pornography) must be interpreted with caution, as covariate analyses do no completely resolve sampling issues [27]. Future research should attempt to replicate the present findings with experimental groups that do not differ on important demographic and individual difference variables.

These data are consistent with theory delineated by Tybur and colleagues [13], which argues that disgust functions to decrease the occurrence (both in the self and society) of sexual behaviors that are perceived as increasing risk of pathogen transmission. Relatedly, and as noted by Haidt and Graham [11], conservative attitudes are driven not only by harm avoidance, but also by concerns about purity. According to these theories, shifts toward politically conservative views on sex may be basic, adaptive, and self-protective responses against perceived spread of pathogens or moral threats. When disgust is evoked, the behavioral immune system engages avoidance to prevent infection (e.g., less interpersonal contact [28]) and appears to moralize sexual conduct in ways that underlie conservative values of purity and sanctity [11,26]. As seen in the results of our study, it is possible that exposure to a disgusting odorant caused increased feelings of disgust, which in turn activated the harm avoidance system and motivated a desire for purity (cleanliness). Once these two systems were activated, it is possible that participants began to adopt attitudes that they perceived as decreasing social harm and/or increasing moral purity.

There is a growing literature indicating that disgust has important consequences for political views and policy preferences. In the research presented here, exposure to a disgusting odor caused greater endorsement of conservative views, including: rejecting gay marriage, restricting sex to marriage, disapproving of the use of pornography, and increased beliefs in Biblical truth.

Odor induced conservative shifts concerning gay marriage were particularly robust. It is possible that some forms of political conservatism, particularly those related to sex and sexuality, are basic and inherent in some populations and can readily emerge under threatening or taxing conditions [4,29,30].

Abstract:

Background: Subthreshold depression is a risk factor for major depressive disorder, and it is known to have a negative impact on quality of life (QOL). Although behavioral activation, which is one type of cognitive behavioral therapy, is an effective psychological intervention for subthreshold depression, neural mechanisms of behavioral activation are unclear. Enhanced functional connectivity between default mode network (DMN) and the other regions has been

ACCEPTED MANUSCRIPT

demonstrated in participants with subthreshold depression. The purpose of this study was to examine the effects of behavioral activation on DMN abnormalities by using resting-state functional MRI (rs-fMRI).

Methods: Participants with subthreshold depression (N=40) were randomly assigned to either an intervention group or a non-intervention group. They were scanned using rs-fMRI before and after the intervention. Independent component analysis indicated three subnetworks of the DMN.

Results: Analyzing intervention effects on functional connectivity of each subnetwork indicated that connectivity of the anterior DMN subnetwork with the dorsal anterior cingulate was reduced after the intervention. Moreover, this reduction was correlated with an increase in health-related QOL.

Limitations: We did not compare the findings with healthy participants. Further research should be conducted by including healthy controls to verify the results of this study.

Conclusions: Mechanisms of behavioral activation might be related to enhanced ability to independently use the dACC and the DMN, which increases an attention control to positive external stimuli. This is the first study to investigate neural mechanisms of behavioral activation using rs-fMRI.

1. Introduction

ACCEPTED MANUSCRIPT

Recently, it has been suggested that subthreshold depression, which is defined as clinically significant depressive symptoms not meeting diagnostic criteria for major depressive disorder (MDD: Pincus et al., 1999), is a potential risk factor for MDD (Bertha and Balázs, 2013; Jinnin et al., 2017). This condition is frequently observed among adolescents, and it is known to have a negative impact on quality of life (QOL: Bertha and Balázs, 2013). Although symptoms of subthreshold depression are less severe than those of MDD, the resulting impairments of daily life functions, including the deficit in QOL is similar to that in individuals with MDD, and significantly worse than in healthy people (Nierenberg et al., 2010). As a result, it is considered essential to elucidate the pathogenic mechanisms of subthreshold depression and to develop effective interventions. In particular, psychotherapy might be preferable for certain groups such as subthreshold cases or adolescents.

A meta-analysis (Cuijpers et al., 2007) suggested that cognitive behavioral therapy (CBT) is an effective intervention for subthreshold depression. Moreover, our previous study (Takagaki et al., 2014) on behavioral characteristics of subthreshold depression demonstrated that people with subthreshold depression are hyposensitive to reward. Therefore, a primary goal of interventions for subthreshold depression is to increase access to positively reinforcing events and activities. Behavioral activation is a CBT technique used for increasing the frequency of positive activities that lead to reinforcements in their life (Jacobson et al., 2001). The efficacy of behavioral activation matched to behavioral characteristics of clients with subthreshold depression has been confirmed in our recent randomized controlled trial (Takagaki et al., 2016), which demonstrated that behavioral activation was effective for improving depressive symptoms as well as clinical variables such as health-related QOL and the exposure to environmental

Accepted manuscript

ACCEPTED MANUSCRIPT

rewards (Takagaki et al., 2016). However, the underlying neural mechanisms of behavioral activation that are associated with the improvement of clinical variables are not fully understood.

A number of resting-state functional magnetic resonance imaging (rs-fMRI) studies that examined functional abnormalities of the brain and therapeutic responses in MDD have reported that depressed patients exhibit hyperactivity of the default mode network (DMN), which is composed of the medial prefrontal cortex (MPFC), the precuneus/posterior cingulate cortex (PCC), the inferior parietal lobule (IPL) and the hippocampal formation (Buckner et al., 2008). According to meta-analysis (Sundermann et al., 2014b), increased functional connectivity in the DMN regions, including the region between the anterior cingulate cortex (ACC) and the medial frontal cortex, as well as the region between the precuneus and PCC, was associated with depression. It is considered that the DMN is associated with self-referential processing (Lemogne et al., 2010). Patients with MDD often show abnormal self-focus biases, such as depressive ruminations (Grimm et al., 2009) and they focus on negative self-relevant information (Nolen-Hoeksema, 2000). Moreover, the functional connectivity between the DMN, including the ventrolateral and ventromedial prefrontal cortices, superior temporal gyri and limbic areas, and subgenual ACC, has the highest power to discriminate MDD patients from healthy controls (Zeng et al., 2014). Therefore, the DMN connectivity is considered to play a central role in the physiopathology of depression (Li et al., 2013).

Moreover, DMN activity of depressive people is known to be abnormally linked to other brain regions. Hwang et al. (2016) demonstrated that subthreshold depression was associated with enhanced functional connectivity between the DMN and regions outside the DMN, similar

Accepted manuscript

ACCEPTED MANUSCRIPT

to patients with MDD (Greicius et al., 2007). Moreover, changes in functional connectivity of the DMN were observed in an early stages of developing MDD, which might be associated with the behavioral characteristics of subthreshold depression. Therefore, investigating whether such abnormalities in the DMN are changed by behavior activation is important for understanding the neural mechanisms of behavior activation in subthreshold depression. However, to date, there are no published studies that have specifically focused on changes in spontaneous brain functions during the course of psychological treatment of subthreshold depression.

The purpose of this study was to examine the neural effects of behavioral activation on the DMN in people with subthreshold depression using rs-fMRI. The DMN can be divided along the anterior-posterior and inferior-superior axes (Allen et al., 2011). Li et al. (2013) investigated changes in the DMN subnetworks of MDD patients following antidepressant treatment, by using independent component analysis (ICA) approach. They reported that abnormalities in the posterior subnetwork were normalized after treatment, whereas there were no changes in the anterior subnetwork. CBT techniques including behavioral activation are mainly known to affect the frontal areas of the brain including the dorsal, ventral, and medial frontal cortices (DeRubeis et al., 2008; Goldapple et al., 2004; Ritchey et al., 2011; Yoshimura et al., 2014). A recent study (Shou et al., 2017) and a review (Mason et al., 2016) of predictors and mechanisms of CBT have also reported that evidence of functional connectivity resulting from CBT was most commonly found in fronto-limbic circuitry. Therefore, we hypothesize that successful behavioral activation would induce changes in functional connectivity of anterior DMN subnetwork. Based on this hypothesis and the method of previous studies (Li et al., 2013), we used only the anterior

Accepted manuscript

ACCEPTED MANUSCRIPT

and posterior subnetworks in the analyses. We did not focus on the temporal lobes, which are also considered to be key regions within the DMN.

2. Methods

2.1. Participants

Participants with subthreshold depression were recruited among freshmen attending Hiroshima University (age = 18 to 19) as diagnosed by the Beck's Depression Inventory-II (BDI-II: Kojima and Furukawa, 2003) and the Japanese version of the Composite International Diagnostic Interview (CIDI: Kawakami et al., 2005). Participants scoring 10 or more points on the BDI-II at all three time points [screening (week 0): $M \pm SD$ = 19.30±4.27, range=14 to 31, conducing the CIDI (week 20): $M \pm SD$ =16.28±4.53, range=10 to 30, and pre-intervention fMRI scanning (week 25): $M \pm SD$ =15.4±3.96, range= 10 to 27] were considered as having subthreshold depression. Participants that met the following criteria after the CIDI conducted by evaluators blind to the subject's assigned group were excluded from this study: (a) major depressive episode within the past one year, (b) a lifetime history of bipolar disorders, (c) taking psychopharmacological or psychological treatment within the past year, and (e) possibility of acute suicide attempts. The remaining participants with subthreshold depression (n =40) were included in the study and were randomly assigned to either an intervention (n =19) or a non-intervention group (n =21).

The intervention group took part in five, weekly, behavioral activation sessions that were conducted by a trained therapist for 60 min per session. The Behavioral activation program (Takagaki et al., 2016) was focused on expanding positively reinforcing activities in order to

Accepted manuscript

ACCEPTED MANUSCRIPT

increase the rate of response-contingent positive reinforcement. First, participants learned to assess their long and short-term goals, and to develop activity monitoring based on psycho-education about depression and behavioral activation (Session 1). Next, they constructed a behavioral ranking consisting of 10 tasks that gave participants a sense of reward (Session 2). Sessions 2–4 focused on behavioral experiments and increasing scheduled activities. In the last session (Session 5), they reviewed behavioral activation and developed a coping behavior plan for stressful situations in the future. Sessions 1-4 included homework. We have already conducted a randomized controlled trial to confirm the effectiveness of this program for late adolescents with subthreshold depression (Takagaki et al., 2016). This program is highly effective in significantly reducing depressive symptoms (Hedges' g =-0.90) and increasing health-related QOL (Hedges' g =0.57-0.77). Participants in the intervention group completed clinical measures, and rs-fMRI scanning was conducted at pre and post intervention. None of the subjects were absent for any of the sessions. They completed all of their homework assignments. Furthermore, a trained therapist conducted the intervention, and adherence to the protocol was assessed as being 100% by two supervisors (for details see, Takagaki et al., 2016). The non-intervention group also participated identically in the study, with the exception of the intervention program. All participants provided their written informed consent before participating in the study. The study was approved by the ethics committee of Hiroshima University.

Accepted manuscript

2.2. Clinical measures

2.2.1. Japanese version of the Beck's Depression Inventory-II (BDI-II)

ACCEPTED MANUSCRIPT

The BDI-II is widely used scale for assessing symptoms that consist of 21 self-report items. The items are scored using a 4-point scale. The Japanese version of the scale has demonstrated reliability and validity (Kojima and Furukawa, 2003).

2.2.2. Japanese version of the Behavioral Activation for Depression Scale (BADS)

The BADS (Kanter et al., 2007) measures the frequency of activation, and consists of 25 items that are rated on a 7-point scale (0: Not at all to 6: Completely). Four subscales of BADS are Activation (AC: 7 items) representing focused, goal-directed activation and completion of scheduled activities, Avoidance/Rumination (AR: 8 items) representing avoidance of negative aversive states and engaging in rumination, Work/School Impairment (WS: 5 items), and Social Impairment (SI: 5 items). We used only the BADS-AC subscale, because our program focused on increasing access to positively reinforcing activities to improve the rate of response-contingent positive reinforcement. The Japanese version of the BADS has demonstrated reliability and validity (Takagaki et al., 2013).

Accepted manuscript

2.2.3. Japanese version of Environmental Reward Observation Scale (EROS)

The EROS (Armento and Hopko, 2007) is used to assess exposure to environmental rewards deemed essential for increasing response-contingent positive reinforcement. Items were composed of behaviors and positive affects as a consequence of rewarding environmental experiences (Armento and Hopko, 2007). The original version of the scale consists of 10 items that are scored on a 4-point scale (1: Strongly disagree to 4: Strongly agree).The Japanese version of EROS has demonstrated reliability and validity (Kunisato et al., 2011).

ACCEPTED MANUSCRIPT

2.2.4. Japanese EuroQOL-5 Dimension (EQ-5D)

The EQ-5D (Euroqol Group, 1990) was developed to assess health-related quality of life and consists of 5 self-report items (3-point scale) and a visual analogue scale (VAS). The self-report items reflect health scored from 0 (death) to 1 (perfect health). VAS evaluates health status as ranging from 0 (worst imaginable health state) to 100 (best imaginable health). The Japanese version of the EQ-5D has demonstrated reliability and validity (Nishimura et al., 1998).

2.3. fMRI data acquisition

Imaging data were acquired using a 3.0 T SIEMENS MAGNETOM with a 12-channel head coil (Siemens, Munich, Germany). Resting-state echo planar imaging (EPI) acquired for approximately 10 minutes for each participant (40 slices; TR/TE = 2500/30 ms; thickness = 3.2 mm; FOV = 212 x 212 mm; flip angle = 80°; matrix = 64 x 64; 244 volumes). During the rs-fMRI scans, participants were instructed to keep looking at a central fixation point, to keep still, to stay awake, and not to think about anything specific. Anatomic T1-weighted images were acquired using an MPRAGE sequence (192 slices; TR/TE = 2300/2.98 ms; thickness = 1 mm; FOV = 256 x 256 x 192 mm; flip angle = 9°; matrix = 256 x 256). All participants had not used nicotine or alcohol because the law prohibits people under 20 from taking these substances in Japan, and these compliances were confirmed by the investigators. Moreover, participants had not used caffeine at least 3 days prior to the scanning session.

Accepted manuscript

ACCEPTED MANUSCRIPT

2.4 fMRI data preprocessing

Preprocessing was performed via Statistical Parametric Mapping software (SPM8: www.fil.ion.ucl.ac.uk/spm). The first four volumes of rs-fMRI data were discarded to ensure signal equilibrium and participants' adaptation to scanning noise. After this the remaining 240 images were first time-corrected for each participants (slice timing) and subsequently realigned by using rigid body transformation. The T1-weighted anatomical volume was coregistered to the mean image created by the realignment procedure and was normalized to the Montreal Neurological Institute (MNI) space using a tri-linear interpolation. All functional images were then smoothed using 6-mm full-width at half-maximum Gaussian kernel.

2.5 Independent component analysis and selection on networks-of-interest

We performed group-ICA using the GIFT-software (http://icatb.sourceforge.net/l). ICA is a data-driven technique for identifying functional connectivity patterns in resting-state fMRI (Beckmann, 2012). As head motion may have both noise and neuronal effects on functional connectivity measures (Satterthwaite et al., 2012; Ling-Li. Zeng et al., 2014), we confirmed that there were no differences in head motion parameters by comparing the groups as well as pre-intervention and post-intervention before performing ICA. Based on previous studies (Allen et al., 2011; Manoliu et al., 2013), we decomposed our data into 75 components based on the infomax-algorithm (Calhoun et al., 2001). It has been demonstrated that decomposing into 75 components is optimal for detecting between-group differences and for avoiding false positive results (Abou-Elseoud et al., 2010). The reliability and robustness of the estimated components were subsequently maximized by running 20 iterations of the ICA using the ICASSO toolbox

Accepted manuscript

ACCEPTED MANUSCRIPT

(Himberg et al., 2004). Then, to identify DMN components, we performed multiple spatial regression analyses on spatial maps of the 75 components using three DMN templates, reflecting anterior, inferior posterior, and superior posterior subnetworks. These templates were chosen from T-maps of 28 resting-state networks available on Internet (Allen et al., 2011: http://mialab.mrn.org/data/hcp/RSN_HC_unthresholded_tmaps.nii). We selected the three DMN components having the highest correlation coefficients (component 13: 0.47, $p < .05$; component 56: 0.45, $p < .05$; component 39: 0.32, $p < .05$) with the templates. The amplitude of each component is known to reflect the contribution of each voxel to the distribution and the coherent activity within that component and therefore, it is interpreted as a functional connectivity (Manoliu et al., 2013).

Accepted manuscript

2.6. Statistical analyses

Voxel-wise one-sample *t* tests were used to identify the spatial pattern of each DMN component (multiple comparisons with $p < .05$ family-wise-error correction on the peak- and cluster-level). We then used the mask obtained from one-sample *t* test results corresponding to each components for the following brain analysis. Each mask was created by combining the spatial maps of the two groups obtained from one-sample *t* test results for each components within intervention and non-Intervention groups, respectively. Intervention effects on clinical states such as depressive symptoms were examined by using two-way analyses of covariance (ANCOVAs), with groups and time points as independent variables and clinical scores (e.g. BDI-II) as dependent variables. Age and gender were included in the analyzed model as covariates. Bonferroni corrected post-hoc tests ($p < .05$) were conducted to specify significant

group and time effects. For the whole brain analysis, we decided on a cut off threshold of p <.001 uncorrected and a spatial extent of 10 voxels (k >=10) to avoid Type II errors (Lieberman and Cunningham, 2009). And similar ANCOVA models were applied to the amplitude of the voxels within each component in order to examine the effect of the intervention on each DMN component. Finally, we calculated correlations between the degree of changes in functional connectivity, by subtracting the pre-component image from the post-component image using ImCalc on SPM within the resulting areas of ANCOVAs interaction, and clinical scores within each group. The statistical threshold for these correlation analyses was set at $p < .05$.

ACCEPTED MANUSCRIPT

3. Results

3.1. Subnetworks of the DMN in subthreshold depression

Three components of the DMN subnetworks were identified in all participants (Figure 1): component 13 representing the anterior DMN (aDMN) had the highest amplitude in ACC and MPFC, component 56 representing the inferior posterior DMN (ipDMN) had the highest amplitude in PCC, and component 39 representing the superior posterior DMN (spDMN) had the highest amplitude in precuneus.

Accepted manuscript

3.2. Intervention effects on clinical scores

Results of ANCOVAs conducted on scores of most clinical scores assessment scales (BDI-II, BADS-AC EROS and VAS of EQ-5D) showed significant interactional effects between group and time (Table 1; BDI-II: $F(1, 36) = 7.34$, $p < .05$, *partial* $\eta^2 = 0.17$; BADS-AC: $F(1, 36) = 26.00$, $p < .001$, *partial* $\eta^2 = 0.42$; EROS: $F(1, 36) = 6.67$, $p < .05$, *partial* $\eta^2 = 0.16$; VAS of EQ-5D:

ACCEPTED MANUSCRIPT

$F(1, 36) = 12.23$, $p < .001$, *partial* $\eta^2 = 0.25$). Post-hoc analysis with Bonferroni correction indicated significantly lower BDI-II and higher EROS and VAS scores at post-intervention in the intervention group compared to the non-intervention group (BDI-II: $p < .01$, *partial* $\eta^2 = 0.14$; EORS: $p < .05$, *partial* $\eta^2 = 0.12$; VAS of EQ-5D: $p < .001$, *partial* $\eta^2 = 0.30$). There were also significant improvements in the intervention group at post-intervention compared to pre-intervention (BDI-II: $p < .001$, *partial* $\eta^2 = 0.36$; BADS-AC: $p < .001$, *partial* $\eta^2 = 0.55$; EROS: $p < .01$, *partial* $\eta^2 = 0.24$; VAS of EQ-5D: $p < .01$, *partial* $\eta^2 = 0.19$). BADS-AC score of the non-intervention group at pre-intervention was higher than that of the intervention group ($p < .01$, *partial* $\eta^2 = 0.18$). Therefore, we used the BADS-AC score at pre-intervention as a covariate in the subsequent analysis. These ANCOVAs are described in the next section. Moreover, there was a significant reduction of VAS in the non-intervention group ($p < .05$, *partial* $\eta^2 = 0.11$).

3.3. Changes in DMN subnetworks after behavioral activation

The results of ANCOVAs are shown in Figure 2. It can be seen that there is a significant interactional effect in the dorsal ACC (dACC) within the aDMN component ($p < .001$ uncorrected, $k >= 10$). Figure 2B shows the coherent activity of the dACC within the aDMN component, which implies a functional connectivity between the dACC and this component, in both groups at each time point. Post-hoc analysis revealed that the aDMN-dACC connectivity was significantly reduced in the intervention group ($p < .001$ uncorrected, $k >= 10$). There were no significant interactions, or main effects of group or time in the ipDMN or the spDMN.

3.4. Correlations of the DMN subnetworks with clinical scores

Accepted manuscript

ACCEPTED MANUSCRIPT

We conducted correlation analyses with differences between pre and post intervention in aDMN-dACC functional connectivity and clinical data in order to explore associations between changes in aDMN-dACC connectivity and treatment response. We found a significant negative correlations between change in aDMN-dACC functional connectivity and VAS changes of EQ-5D in the intervention group (Figure 3: $r = -.61$, $p < .01$), which remained significant after controlling for BDI-II score ($r = -.62$, $p < .01$). Other clinical scores were not correlated with change of the aDMN-dACC functional connectivity either both group (BDI-II: $r = .12$, *n.s.*, $r = -.17$, *n.s.*; BADS-AC: $r = -.02$, *n.s.*, $r = .36$, *n.s.*; EROS: $r = .08$, *n.s.*, $r = .06$, *n.s.*; EQ-5D: $r = -.23$, *n.s.*, $r = .10$, *n.s.*; intervention and control group, respectively).

Accepted manuscript

4. Discussions

There were two main findings of this study. Firstly, among the three subnetworks of the DMN that identified by ICA in participants with subthreshold depression, behavioral activation might have specifically reduced the functional connectivity in the aDMN subnetwork with the dACC at least compared to non-intervention, although it is not possible to make any inferences about causation. Secondly, the reduction in the connectivity between the aDMN and the dACC was negatively correlated with the increase in subjective health-related QOL of the intervention group. This is the first study using rs-fMRI to report the effect of behavioral activation on spontaneous brain functions in people with subthreshold depression.

Decreased functional connectivity between the aDMN and the dACC following behavioral activation, implies that activity pattern of the dACC was de-synchronized with the time series of

ACCEPTED MANUSCRIPT

our aDMN component. On the other hand, behavioral activation had no effect on posterior subnetworks of the DMN (i.e. the ipDMN, or the spDMN). Antidepressants and psychotherapy (e.g. cognitive therapy) is known to work through different mechanisms (DeRubeis et al., 2008). A number of previous studies that examined neural responses to CBT have demonstrated functional brain changes in the dorsal, ventral, and medial frontal cortices (DeRubeis et al., 2008; Goldapple et al., 2004; Ritchey et al., 2011; Shou et al., 2017; Yoshimura et al., 2014) and dorsal/pregenual ACC (Fu et al., 2013; Konarski et al., 2009) related to treatment. CBT-related changes were most commonly observed in the DMN regions, which include the MPFC, PCC, hippocampus, and ACC sub-regions including dorsal, subgenual, and ventral (as review: Franklin et al., 2015). As already mentioned, DMN connectivity is deeply involved with depressive self-referential processing such as rumination (Li et al., 2013; Sundermann et al., 2014a; Ling-Li Zeng et al., 2014). Moreover, the decrease in dACC activity at resting-state following CBT could be conceptualized as the result of CBT improving a putative 'dorsal cognitive circuit', important in cognitive control and effortful regulation of emotion (Franklin et al., 2015). These findings might suggest that there is a neural circuit of behavioral activation in common with CBT. Whereas one previous study has shown that antidepressants act on the posterior DMN (Li et al., 2013). Goldapple et al. (2004) reported that depressed subjects have shown decreases of activation in the dorsal, medial and ventral prefrontal cortices, in addition to increases of activation in the hippocampus and in the dorsal cingulate cortex after CBT. They also obtained different patterns after paroxetine treatment, including increases in the prefrontal cortex and decreases in the hippocampus and subgenual cingulate. A subsequent study by Kennedy et al. (2007) compared CBT to venlafaxine and replicated these findings, which again suggested different

Accepted manuscript

types of neural changes following CBT and pharmacotherapy. Unlike other psychiatric disorders, including obsessive-compulsive and panic disorders, the mechanisms of pharmacological medication and psychotherapeutic treatment in depression seem to be divergent, or only partly overlapping (Barsaglini et al., 2014). Our results suggested that behavioral activation might act differently to pharmacotherapy, by changing the anterior subnetwork of the DMN, which supported our hypothesis and findings of previous studies investigating the neural responses to CBT.

Generically speaking, the dACC is known as a core region of the salience network (SN: Menon and Uddin, 2010), which is typically distinguished from the DMN. However, in this study, ICA analysis of our data on participants with subthreshold depression identified the DMN and the dACC as identical component. ICA is a data-driven analysis method and our data points were composed mainly of subjects with subthreshold depression who had not been subjected to an intervention (pre-intervention and non-intervention conditions), which resulted in the dACC being included in the aDMN "component". It has been reported that increased functional connectivity is observed between the DMN and other regions, which the included bilateral middle frontal gyrus, left superior frontal gyrus, right inferior frontal gyrus, ventral striatum, thalamus, parahippocampus, and insula, in people with subthreshold depression (Hwang et al., 2016) and that functional connectivity between the DMN and the SN is stronger in patients with MDD than in healthy participants (Manoliu et al., 2013). These findings suggested that enhanced functional connectivity between the DMN and the dACC in the SN might be closely associated with the pathology of subthreshold depression. The SN, which anchors the dACC and the anterior insula, is known to be involved in the detection of salient stimuli and events(Seeley et al., 2007) in order to guide behavior (the ACC is involved in action selection in particular:

ACCEPTED MANUSCRIPT
Accepted manuscript

ACCEPTED MANUSCRIPT

Rushworth, (2008)), and play a central role in biased negative informative processing in depression (Hamilton et al., 2012). High aDMN-dACC connectivity during the resting-state might reflect co-working of internal self-reference processing (DMN) and the detection of these internal stimuli (SN). In addition, the SN critically contributes to switching between the DMN and the executive network, so the dACC and anterior insula are uniquely positioned to initiate control signals that deactivate the DMN and activate the executive network (Seeley et al., 2007). Therefore, individuals with enhanced connectivity of the two networks, DMN and SN, might be contribute to directing attention to internal-self stimuli, without awareness of external stimuli as a consequence of deactivation in the executive network that contributes to the control of active attention. Again, our results revealed that the contribution of the dACC absorbed in the aDMN component has decreased following behavioral activation. This indicated that the dACC might not have been included in the aDMN component after intervention, as it is originally defined. Our behavioral activation program was developed for the purpose of increasing participants' access to positive activities, which was accompanied by reinforcements from their environment (Takagaki et al., 2016). Results indicated an increase in these activities and an increase in exposure to environmental rewards (Table 1), suggested that this purpose was adequately achieved. The dACC would be activated when detecting the reward and selecting behavior, and would be required to control aDMN deactivation. Such practices might have increased opportunities for activating the dACC and deactivating the DMN. The mechanisms of behavioral activation might be related to enhanced ability to independently use the dACC and the DMN, which advanced the control of attention favoring positive stimuli from the external

ACCEPTED MANUSCRIPT

environment. The use of a placebo and comparison with other psychotherapies are expected to further clarify this interesting mechanism.

The dACC plays a critical role in the development of cognitive control skill that are required for adaptive functioning (Ordaz et al., 2013). Moreover, it is known that dACC activity increases with aging (Rubia, 2013) from childhood (9-17 years) to adulthood (18-26 years). One model of adolescent brain development (Crone and Dahl, 2012) describes the gradual development of the cognitive control system (dACC, dorsolateral PFC and the parietal cortex) interacting with social-affective processing and leading to increased adaptive adult functioning such as social motivation and tendencies to explore, take risks and try new things. Additionally, within-functional networks (including the DMN) are enhanced during development from early adolescence to late adolescence (Fair et al., 2008; Kelly et al., 2009; Saverino et al., 2015). A recent study on enhanced connectivity of depressed youth in remission (Jacobs et al., 2014) has also reported hyper-connectivity of the DMN and SN, whereas young adolescents with depression did not shown significant differences in resting-state DMN connectivity compared to health young adolescents (Pannekoek et al., 2014). Because the participants in this study were late adolescents, changes in DMN-dACC connectivity might be critical to many domains of adaptive adult functioning. Therefore, we suggest that future studies investigate other age groups such as children and adults with and without depression by using the research design developed in this study.

Accepted manuscript

Certain late adolescents with subthreshold depression show increased depressive symptoms and develop a major depressive episode during the natural course of one year (Jinnin et al., 2017). Therefore, it is significant that behavioral activation results in positive changes in many clinical variables for late adolescents. Results also indicated an association between

changes in connectivity within the aDMN component and VAS score of EQ-5D, which is a measure of health-related QOL. This was not the case between connectivity and other clinical variables such as the BDI-II, BADS, or EROS. Recently, QOL has been recognized as a more pertinent outcome measure because improvement of QOL is important in clinical settings as well as improvements of symptoms (Satomura et al., 2014). Individuals with subthreshold depression have lower depressive symptoms than patients with depression. Nevertheless, functional impairments in subthreshold depression are severe and serious (Bertha and Balázs, 2013; Nierenberg et al., 2010). Our previous study (Takagaki et al., 2016) reported that behavioral activation for subthreshold depression improves health-related QOL. Therefore, it is significant that changes in functional connectivity, possible caused by behavioral activation, were linked to the positive effects experienced by the participants. Faget-Agius et al. (2016) investigated brain functions associated with the QOL of schizophrenia patients using whole-brain single photon emission computed tomography in the resting-state. Their result indicated that not only the prefrontal area but also areas of the DMN such as precuneus (Buckner et al., 2008) and areas co-activating with the DMN such as parahippocampal gyrus (Greicius et al., 2003) were related to QOL. Although there are still few studies on the relationship between QOL and brain functions, our results showing that a change in the aDMN-dACC connectivity was associated with health-related QOL also where quite consistent with their results. As discussed in the previous paragraph, the reduction in aDMN-dACC functional connectivity would have advanced the control of attention to positive stimuli, and both the DMN and the dACC are associated with better prediction of treatment outcome (Fu et al., 2013; Ritchey et al., 2011). It is possible that increased awareness of positive stimuli in the

ACCEPTED MANUSCRIPT
Accepted manuscript

ACCEPTED MANUSCRIPT

reward acquisition process, which was associated with a reduction in aDMN-dACC connectivity following our behavioral activation program might result in an enhanced outlook on health in life.

The results of this study are constrained by several limitations. Firstly, we did not compare the enhanced functional connectivity between the DMN and the dACC found in people with subthreshold depression with healthy participants. Moreover, we used thresholds recommended for balancing Type I and Type II error (Lieberman and Cunningham, 2009). Our findings must be considered preliminary because we did not use correction methods for multiple comparisons. The detection of intervention effects should be re-examined using more severe thresholds or correction for multiple comparisons to avoid Type I errors. Although abnormal change in functional connectivity of the DMN in people with subthreshold depression have already demonstrated in a previous study (Hwang et al., 2016), further research should be conducted by including healthy controls to verify the results of this study. Second, we did not examine the function of aDMN-dACC using measures of directing attention to internal-self stimuli, or awareness of external stimuli. There is a need to conduct a mediation analysis, particularly with regard to the association with health-related QOL. Nevertheless, we could not conduct such a mediation analysis because of the small sample size. The assessments of such psychological functions are necessary in order to examine the consideration that we have stated in the discussion. Thirdly, the lack of a placebo group makes it difficult to attribute the findings of this study to any specific treatment effects. This is because the effects of other specific factors, known to be related to the treatment efficacy of psychotherapy independently of its orientation (CBT, Psychodynamic treatment etc.) cannot be discounted. Fourth, we focused on subthreshold

Accepted manuscript

depression and did not include clinical course data (e.g. development of MDD) in our analyses. The study how behavioral activation and brain function are related to future depression is also required in the future. Finally, our sample was not population-based, and participants were students of the same university, limiting the generalizability of our findings. Nevertheless, the homogeneity of the sample might also be a strength of this study because it diminished the possible effects of demographic variables as confounds.

ACCEPTED MANUSCRIPT

5. Conclusions

Behavioral activation induced a specific reduction in functional connectivity between the aDMN subnetwork and the dACC compared to the non-intervention group, which was negatively correlated with an increase of subjective health-related QOL in the intervention group. Mechanisms of the therapeutic efficacy of behavioral activation might be related to enhancing the ability for independently using the dACC and the DMN, which might advance an attention control directed at positive stimuli in the external environment. These findings contribute to our understanding of neural mechanisms of behavioral activation on subthreshold depression.

Abstract

Convincing evidence shows that stress is associated with the development and course of psychiatric and metabolic disorders. The hypothalamic-pituitary-adrenal (HPA) axis mediates the stress response, a cascade of events that culminate in the release of glucocorticoids from the adrenal cortex. Chronic hypercortisolism typically characterizes stress-related illnesses, such as depression, anxiety, and metabolic syndrome. Considering previous studies pointing that environmental enrichment (EE) mitigates the deleterious effects of stress on neurobiological systems, we hypothesized that EE can confer resiliency against prolonged glucocorticoid administration-induced behavioral and metabolic alterations in mice. In this regard, three-month-old male Swiss mice were exposed to a four-week period of standard environment (SE) or EE. After this period, still in the respective environments, dexamethasone was administered intraperitoneally (i.p.) at a dose of 4 mg/kg, for 21 consecutive days, in order to generate the emotional-related behavioral outcomes, as previously described. It is demonstrated herein that EE prevents the dexamethasone-induced anxiety-like and passive stress-coping behaviors, as observed in the open field and tail suspension tests. Moreover, EE mitigated the hyperproteinemia and body weight loss induced by excess dexamethasone and decreased basal glucose levels. Taken together, these results support the hypothesis that EE attenuates the effects of chronic administration of synthetic glucocorticoids in mice, a strategy that may be translated to the clinical perspective.

Keywords: dexamethasone; environmental enrichment; behavior dysfunctions, metabolic dysfunctions.

Introduction

The stress-responsive hypothalamic-pituitary-adrenal (HPA) axis is causally implicated in the development and course of major depressive disorder (MDD) (Keller et al., 2017), being described that patients with depression present HPA-axis overactivity (De Kloet, Joëls & Holsboer, 2005). The untoward consequences of excess cortisol are manifold, ranging from peripheral effects (e.g., glucose intolerance) to adverse effects on brain function. In this regard, hypercortisolemia, as seen in Cushing's disease or after prolonged glucocorticoid administration, can result in depression or emotional lability (Brown et al., 2006; Newell-Price et al., 2006). For instance, chronic dexamethasone administration in adult life (Skupio et al., 2015) or during intrauterine development (Conti et al., 2017) induces a range of depressive-like symptoms in rodents, such as anhedonia, behavioral despair, weight loss, and anxiety-like behavior.

The ability to cope with stress is influenced by multiple factors such as early life experiences, gender, or personality traits (Chen & Baram, 2016). In fact, many environmental factors seem to influence both the physiological functions of the central nervous system and its ability to counteract pathological changes. For instance, negative life events, such as the death of a parent, maternal deprivation, parental abandonment and separation of parents or divorce, can influence the development of mental disorders, such as depression (Juruena, 2013). In laboratory animals, stress reduction may be achieved by enriching the animal's environment with devices that promote its normal instinctive tendencies (Belz et al., 2003). In this regard, environmental enrichment (EE) is an animal housing technique composed of increased space, physical activity, and social interactions, which in turn increases sensory, cognitive, motor, and social stimulation (Nithianantharajah & Hannan, 2006). EE leads to improved cerebral health as defined by increased neurogenesis, enhanced learning and memory and resistance to external cerebral insults (Young et al., 1999). Moreover, living in an EE with physical and social stimulation also leads to improved metabolic health (Cao et al., 2011). Considering previous studies pointing that EE

Accepted Manuscript

mitigates the deleterious effects of stress on neurobiological systems and endocrine profiles (Mitra & Sapolsky, 2009; Lehmann & Herkenham, 2011), the present study hypothesized that EE would prevent the development of behavioral (e.g., depressive and anxiogenic-like effects) and metabolic alterations induced by chronic dexamethasone administration in mice. Thus, in order to evaluate the preventative effects of EE, mice were reared in this condition prior to the dexamethasone exposure.

Methods

Animals

Experiments were carried out on 2-month-old male Swiss albino mice from the animal facility of Universidade Federal de Santa Catarina (UFSC, Florianópolis, Brazil), weighing around 45-55 g at the time of testing. They were kept in groups of 10 animals per cage in a room under controlled temperature (23 ± 1 °C) and subjected to a 12-h light cycle (lights on 6:00 a.m.) with free access to food and water. All procedures comply with the guidelines on animal care of the local Ethics Committee on the Use of Animals (protocol 5497310718).

Drug administration

The synthetic glucocorticoid agonist dexamethasone (Laboratório Teuto, Brazil) was dissolved in saline and administered intraperitoneally (i.p.) at a dose of 4 mg/kg of body weight for 21 consecutive days. The dose of dexamethasone was chosen based on the study by Skupio and colleagues (2015), which demonstrated that chronic dexamethasone administration induces both a range of depressive-like symptoms, such as behavior despair, weight loss, and anxiety-like behavior. The control group received saline injection (0.1 mL per 10 grams of body weight). The treatments occurred between 7:00 and 9:00 a.m.

Accepted Manuscript

Housing Conditions

The standard environment (SE) mice were housed in wire-topped clear plastic cages (38 cm × 32 cm × 17 cm). The EE mice were housed in larger plastic boxes (44 cm × 32 cm × 18 cm), containing a variety of stimuli, e.g., a running wheel, plastic tubing, ladders, rubber balls and a wood shelter, as previously established in or laboratory (de Souza et al., 2019a). These items were moved to different spatial locations of the cage every 3-4 days. The animals were maintained 24 h per day in groups of 10 animals for both SE and EE conditions until the beginning and throughout the duration of the behavioral experiments. Although in several studies the mice designated to the EE cohort were housed in larger groups to allow more social interactions, we kept the same number of animals per cage, as in previous studies of our research group (de Souza et al., 2019a).

Experimental design

Forty male Swiss adult mice were divided into four experimental groups (10 mice per group): standard environment plus saline (SE Saline), standard environment plus dexamethasone (SE Dexa), environmental enrichment plus saline (EE Saline) and environmental enrichment plus dexamethasone (EE Dexa). Animals were exposed to a 28-days period of SE or EE. After this period, still in the respective environments, the animals received daily saline solution or dexamethasone, as previously described, for 21 consecutive days. Body mass was measured daily. On days 47 and 48, still on the influence of the above-mentioned treatments, the animals were submitted to two behavioral tests: tail suspension test (day 47) and open field test (day 48). One day after the last behavioral test, mice were food-deprived for six hours (starting 7 a.m.) and the glucose tolerance test was performed (day 49). A day after (day 50), mice were again food-deprived for six hours, anesthetized with a mixture of ketamine (80 mg/kg, i.p.) and xylazine (10 mg/kg, i.p.), and the blood was collected from the heart to determination of plasma

Accepted Manuscript

triglycerides, cholesterol, total protein, and corticosterone levels. On day 50, no dexamethasone was administered (Figure 1).

Behavioral tasks

All experiments were conducted during the light phase (1:00–6:00 p.m.). Experiments were conducted in a controlled-temperature room (23°C, the humidity was between 40% - 60%), with low-light intensity (12 lx). Moreover, they were recorded (webcam Microsoft VX 3000) and the videos were analyzed using the Ethowatcher® software.

Tail Suspension Test (TST)

The TST measures coping strategy to an acute inescapable stress (Commons et al., 2017). This test was developed by Steru and colleagues (1985) based on the premise that an animal subjected to a stressful and inescapable situation presents two types of alternating behaviors, the agitation characteristic of the attempt to escape from the stressful situation, and immobility. This pattern of behavior can also be called searching-behavior, characterized by the alternation of intense motor activity and energy expenditure with immobility. Mice both acoustically and visually isolated were suspended 30 cm above the floor by adhesive tape placed approximately 1 cm from the tip of the tail. Immobility time was manually recorded during a 6-min period by an experienced observer. The observer was in the room where experiments were performed and were blind to the animal condition.

Accepted Manuscript

Open Field Test (OFT)

The open field was used to evaluate the locomotor and exploratory activities induced by a novel environment. The natural tendency of the animal in a new environment is to exploit it, despite the stress and conflict caused by the new environment (Prut & Belzung, 2003). This test

assess unconditioned emotional reactions based on natural approach/avoidance conflict (Ramos, 2008). The anxiety-related behavior in the OFT is triggered by two factors: individual testing and agoraphobia. Higher levels of anxiety should mainly lead to decreases in the ratio 'number of squares visited in center/number of squares visited on periphery'. The apparatus, made of wood and covered with impermeable Formica, had 50 cm wide × 50 cm deep × 40 cm high. Each mouse was placed in the center of the open field and allowed to freely explore the apparatus for 5 min. The following behavioral parameters were evaluated: % of crosses in the center, total number of crosses and time in the center.

Biochemical analysis

The glucose tolerance test was assessed by i.p. administration of D-(+)-glucose (Sigma Aldrich, St Louis, MO) at a concentration of 2 g/kg body weight. Blood glucose was measured from the tail tip at baseline and 15, 30, 60, and 120 minutes after glucose overload using a glucometer (Accu-Chek Performa®). For the area under the curve (AUC) calculation, it was used the mean baseline value (time 0) for each group (baseline for the area). Total cholesterol, triglycerides, and total proteins were measured in plasma using the enzymatic kit according to the manufacturer's instructions (Gold Analisa, Belo Horizonte, MG, Brazil). The results were expressed as mg/dl.

Statistical analysis

The results are presented as mean + standard error of the mean (SEM). Statistical analyses were carried out using a two-way or three-way analysis of variance (ANOVA). Following significant ANOVAs, multiple post hoc comparisons were performed using Newman Keul's test. P values less than 0.05 ($P < 0.05$) were considered as indicative of significance. All tests were performed using the STATISTICA® software package (StatSoft Inc, Tulsa, OK, USA).

Accepted Manuscript

Results

Open Field Test (OFT)

The two-way ANOVA indicated a significant main effect for treatment [$F(1, 36) = 5.18$, $p < 0.05$] and for housing conditions by treatment interaction [$F(1, 36) = 6.93$, $p < 0.05$] on center time (Fig 2a). Subsequent post hoc comparisons revealed a significant decreased in the time spent in the center of the apparatus in the SE Dexa group in comparison with the SE Saline group and with the EE Dexa group ($p < 0.05$). On the other hand, the two-way ANOVA indicated no significant effects on the percentage of center crossings (Fig 2b) and on the total crossings (Fig 2c).

Tail Suspension Test (TST)

The two-way ANOVA indicated no significant effects on the latency to immobility (Fig 3a). On the other hand, the two-way ANOVA indicated a significant main effect for treatment [$F(1, 36) = 8.58$, $p < 0.05$] and for housing conditions by treatment interaction [$F(1, 36) = 9.65$, $p < 0.005$] on the immobility time in the TST. Subsequent post-hoc analysis revealed a significant increase in the immobility time in the SE Dexa group when compared with the SE Saline group and with the EE Dexa group ($p < 0.05$) (Fig 3b).

Metabolic analysis

The two-way ANOVA revealed a significant main effect for treatment [$F(1, 36) = 27.98$, $p < 0.0005$] and for housing conditions by treatment interaction [$F(1, 36) = 4.06$, $p < 0.05$] on body mass variation (Fig 4a). Subsequent post-hoc analysis revealed a significant loss of body mass (%) in the SE Dexa group when compared with the SE saline group and with the EE Dexa group ($p < 0.05$).

The two-way ANOVA analysis indicated a significant main effect for treatment [$F(1, 36) = 153.86$, $p < 0.0005$] on plasma cholesterol concentration (Fig 4b). Subsequent post-hoc analysis

Accepted Manuscript

revealed a significant elevation on plasma cholesterol concentrations in both the SE Dexa group and the EE Dexa group when compared with their respective saline control groups ($p < 0.05$). On the other hand, the two-way ANOVA indicated a significant main effect for treatment [$F(1, 36) = 5.12$, $p < 0.05$] and for housing conditions by treatment interaction [$F(1, 36) = 6.26$, $p < 0.05$] on plasma triglyceride concentration (Fig 4c). Subsequent post-hoc analysis revealed a significant decrease in triglycerides concentrations in the SE Dexa group when compared with the SE Saline group and with the EE Dexa group ($p < 0.05$). Moreover, the two-way ANOVA revealed a significant main effect for treatment [$F(1, 36) = 5,85$, $p < 0.05$] and for housing conditions by treatment interaction [$F(1, 36) = 5,61$, $p < 0.05$] on plasma total protein concentration. Subsequent post-hoc analysis revealed a significant increase in total protein concentration in the SE Dexa group when compared with the SE Saline group and with the EE Dexa group ($p < 0.05$) (Fig 4d).

The two-way ANOVA analysis indicated a significant main effect for housing conditions [$F(1, 36) = 10.72$, $p < 0.005$] on basal glucose levels (Fig 4e). Subsequent post-hoc analysis revealed a significant decrease on basal glucose levels specifically in the EE Dexa group when compared with its respective saline control group ($p < 0.05$). The three-way ANOVA indicated significant main effects for housing conditions [$F(1, 180)= 11.68$, $p < 0.001$], treatment [$F(1, 180)= 4.81$, $p < 0.05$], time [$F(1, 180)= 11.68$, $p < 0.0001$], and housing conditions by treatment interaction [$F(1, 180)= 11.35$, $p < 0.0005$] (Fig 4f). Subsequent post-hoc comparisons indicated no significant differences among groups at each time point. On the other hand, the two-way ANOVA revealed a significant main effect for treatment [$F(1, 36) = 5.81$, $p < 0.05$] on the area-under-the-glucose-curve (AUC) (Fig 3g) that was based on blood glucose values from Figure 4g.

Accepted Manuscript

Discussion

The present study aimed to investigate the effects of EE on dexamethasone-induced behavioral reactivity and metabolic disturbances in mice. Our findings that chronic dexamethasone treatment induces anxiety-like and passive stress-coping behaviors in mice replicate the findings of the study conducted by Skupio et al. (2015), upon which our experimental protocol was based. Regarding the metabolic effects of dexamethasone, mice presented weight loss, decreased plasma triglycerides levels, increased total plasma proteins, and cholesterol levels and glucose intolerance. Of importance, we demonstrated that EE blunted the dexamethasone-induced behavioral reactivity in the TST and OFT, respectively. EE also mitigated dexamethasone-induced weight loss, hypotriglyceridemia, and hyperproteinemia.

Herein, chronic dexamethasone treatment-induced behavioral despair and anxiety-like behavior in mice, as observed in the TST and OFT, respectively. These findings agree with data observed in the literature. There is compelling evidence that dexamethasone administration, in an acute or chronic regimen, at doses varying from 16 µg/kg to 4 mg/kg, induces depressive-like and anxiety-like behavior in mice (Wróbel et al., 2014; Skupio et al., 2015; De Souza et al., 2019b). Moreover, Pazini et al. (2017) have shown that swiss mice treated with corticosterone, at a dose of 20 mg/kg, for 21 days, showed an increase in the immobility time in the TST. The authors associated such depressive-like effect with decreased hippocampal cell proliferation and neuronal differentiation and increased glial fibrillary acid protein (GFAP) immunostaining (suggestive of astrogliosis) in dentate gyrus (DG) of the hippocampus (Pazini et al., 2017). Moreover, Zhang and colleagues have shown that C57Bl/6 mice treated with corticosterone, at a dose of 40 mg/kg, for 35 days showed significantly less time spent in the center zone of the OFT (Zhang et al., 2016). The behavioral despair and anxiety-like behavior seen here probably reflect the spectrum of mood disorders observed in patients with hypercortisolemia, as in Cushing's syndrome (Newell-Price et al., 2006) and the common comorbidity of depression and anxiety observed in patients (Wu &

Accepted Manuscript

Fang, 2014). In the present study, it was found that treatment with EE mitigated both behavioral despair and anxiety-like behavior induced by dexamethasone in the TST and OFT, respectively. In this regard, previous studies reported that EE decreases corticosterone concentrations in rodents (Belz et al., 2003). In an elegant study, Sztainberg and colleagues (2010) demonstrated that EE significantly reduced CRHr-1 mRNA expression in limbic regions, suggesting a molecular mechanism that might explain the EE effects on decreasing corticosterone concentrations: the downregulation of this receptor decreases the release of ACTH by adenohypophysis and, consequently, decreases the release of corticosterone by the adrenal cortex. Furthermore, Hare and colleagues (2014) showed that four weeks of voluntary wheel running resulted in a shorter time to peak corticosterone concentration and a more rapid decay of plasma corticosterone levels following restrain stress in mice. The authors conclude that exercise renders animals particularly resilient, capable of producing a robust response to stress while limiting the damage that might result from overexposure to glucocorticoids during periods of stress (Hare et al., 2014). Indeed, numerous clinical and experimental studies demonstrated that many environmental factors, such as EE, may affect both the physiological functions of the central nervous system and its ability to counteract pathological changes (Van Praag, Kempermann & Gage, 2000). Of note, the changes provided following EE exposure are commonly described as experience-dependent, indicating that they result from active interaction between the animal and the affordances available in the environment (Nithianantharajah & Hannan, 2006).

Herein it was observed that chronic dexamethasone treatment induced a significant metabolic dysfunction, characterized by glucose intolerance, decreased body weight and plasma triglyceride levels, as well as increased plasma total protein and cholesterol levels. The increase in plasma total protein concentrations is related to the catabolic properties of glucocorticoids, i.e., increasing protein degradation and decreasing protein synthesis in skeletal muscle (Morgan et al., 2016), which may also support the weight loss observed in dexamethasone-treated rodents (Tonolo et al.,

Accepted Manuscript

1988; Noh et al., 2014). This reduction in body weight during dexamethasone treatment is also related to a negative water balance (Thunhorst et al., 2007) and higher levels of anorexigenic insulin levels (Protzek et al., 2014). The dexamethasone treatment also induced a significant decrease in plasma triglyceride concentration. However, in this case, our results diverge from prior findings (Barbosa et al., 2016). For instance, dexamethasone treatment, at a dose of 0.5 mg/kg for 15 days, resulted in a significant increase in triglyceride levels in rats (Barbosa et al., 2016). Although most data have shown that glucocorticoids induce lipolysis and consequently, plasma free fatty acid increases (Divertie et al., 1991), the effects of glucocorticoids on lipid mobilization are still controversial. For instance, some studies report an inhibitory effect of cortisol on lipolytic activity (Ottosson et al., 2000). Of note Chen and colleagues (2018) found a significant decrease of triglyceride in plasma and in the liver of goats after intramuscular administration of dexamethasone, at a concentration of 0.2 mg/kg for 21 days. Finally, the significant increase in plasma cholesterol concentration here observed is in accordance with previous studies. For instance, Kumar and colleagues (2011) showed that dexamethasone administration, at a dose of 10 mg/kg for 8 days, increased the plasma cholesterol levels in rats. Most importantly herein, we demonstrated that EE mitigated the dexamethasone effects on body weight, plasma triglycerides, and total protein levels. EE has a general tendency to increase activity and activity energy expenditure in rodents, which has downstream effects on other aspects of energy balance (Novak et al., 2012). In this regard, it is noteworthy that our EE protocol included a running wheel, and since physical exercise is associated with increased protein synthesis (Tipton & Wolfe, 2001), one may associate with the maintenance of body mass observed in EE dexamethasone-treated mice. After ~ 3 weeks in running well, skeletal muscles (gastrocnemius, tibialis anterior, triceps) of male mice show enhanced citrate synthase activity, a validated biomarker for mitochondrial density in skeletal muscle, resulting in better endurance capacity (Manzanares et al., 2018). Moreover, Barel

Accepted Manuscript

and colleagues showed that run on a treadmill attenuated the dexamethasone-induces muscular glycogen loss, muscular atrophy and body weight loss in rats (Barel et al., 2010).

Glucocorticoids, *per se*, are considered diabetogenic agents, as they may promote an increase in hepatic glucose production and a decrease in peripheral uptake (e.g., in muscle and adipose tissues) (Pasieka and Rafacho, 2016). Because of such properties, up to 60% of patients with Cushing's syndrome, characterized by hypercortisolemia, have glucose intolerance (Newell-Price et al., 2006). The glucose intolerance caused by dexamethasone treatment in our study is in agreement with previous studies (Pandey et al., 2014; Lee et al., 2018). The reduction of insulin-stimulated protein kinase B phosphorylation in skeletal muscle seems to be consensual at this chronic dexamethasone exposure (Pandey et al., 2014, Lee et al., 2018), which can imply in reduced glucose disposal. Despite to be not effective in preventing the glucose intolerance caused by glucocorticoids, EE significantly improved the basal glycemic values and kept blood glucose levels bellow of that observed in dexamethasone-treated mice in SE during all period of the test. In this regard, McMurphy and colleagues (2018) observed that EE exposure induces a robust reduction of brown and white adipose tissue, in addition to decreasing hepatic steatosis, hepatic glucose production and increasing glucose uptake by the liver and adipose tissue, contributing to glycemic control in mice. Specifically, the authors demonstrated that EE induced a significant reduction in the expression of two important enzymes involved in the gluconeogenesis pathway, phosphoenolpyruvate carboxykinase 1 (PCK1) and glucose-6-phosphatase (G6PC) (McMurtphy et al., 2018). The apparent lack of effect of EE upon beta cell function may be due to the genomic impact of dexamethasone on insulin secretory machinery of beta cells (Lambillotte et al., 1997). Although we do not discard new approaches of EE aiming to be more effective, we consider EE as a valuable tool for improvement of neurometabolic outcomes as previously demonstrated in a model of glucose intolerance associated to hypercholesterolemic diet where EE mitigated the glucose intolerance (De Souza et al., 2019a).

Accepted Manuscript

An inevitable limitation of our study is that multiple sensory, social, and physical activity factors are typically combined in the EE treatment, making it difficult to determine which of the various enrichment factors or the interaction contributes to the observed effects on behavioral and metabolic outcomes. In this regard, it is not possible to distinguish between the effects of EE *vs* exercise alone, since a running wheel was provided. Of note, McMurphy and colleagues (2018) evaluated the extent to which physical activity is the responsible for the EE-induced healthy aging. In that study, the gene expression profile of the major organs involved in systemic glucose homeostasis (liver, fat and muscle) revealed distinct patterns between EE and running wheel animals, where animals exposed to running wheel showed minor changes in these parameters (McMurphy et al., 2018). Thus, it is noteworthy that no social interaction, novelty, or any other single variable can account for all of the effects of EE (van Praag et al., 2000).

Conclusion

Collectively, our results reproduce the depressive- and anxiety-like behavior caused by supraphysiologic doses of dexamethasone in Swiss male mice, as well as metabolic disturbances (glucose intolerance, hyperproteinemia, hypercholesterolemia, and body weight loss). Most importantly, EE mitigates the depressive- and anxiety-like behaviors. Moreover, our findings suggest that EE is able to promote healthier metabolic function in mice, even in situations of chronic administration of synthetic glucocorticoids. It is noteworthy, however, that although our results reinforce the positive infuences of EE on stress response, the interpretation of our data should be seen as prophylactic rather than therapeutic since EE started before the dexamethasone treatment. Taken together, our results support the hypothesis that EE enhances resilience to stressors, such as the chronic administration of synthetic glucocorticoids used herein, a strategy that may be translated to the clinical perspective. Both, behavioral and metabolic improvements, are of particularly importance, since the prevalence of metabolic disturbance is 58% higher in

Accepted Manuscript

psychiatric patients than in the general population, which suggests that metabolic disturbance is a general comorbidity seen in different psychiatric patient groups, including patients with major depressive disorder (Vancampfort et al., 2015) and anxiety disorder (Tang et al., 2017).

MILLENNIUM ARTICLE

Is there an evolutionary mismatch between the normal physiology of the human dopaminergic system and current environmental conditions in industrialized countries?

L Pani

CNR Center for Neuropharmacology, 'BB Brodie' Department of Neuroscience, University of Cagliari and Neuroscienze Scarl, Cagliari, Italy

A large body of evidence has recently defined a field theory known as 'evolutionary mismatch', which derives its attributes largely from the fact that current environmental conditions are completely different from those in which the human central nervous system evolved. Current views on the evolutionary mismatch theory lack, however, any attempts to define which brain areas or neuronal circuits should be mostly involved in coding such misevolved traits and to what extent our neurobiological knowledge can be applied to the topographical localization of a specific psychopathology. In this respect the mesocorticolimbic dopaminergic circuits have long been misconceptualized as simple reward or reinforcement systems. Instead, they motivate and coordinate the functions of the higher brain areas that mediate planning and foresight and direct finalized movement in both animals and humans. These systems make animals intensely interested in exploring the world around them, but by the same means they also make them susceptible to the environmental stimuli that have been sought and consumed. It is has been speculated that the cortical dopamine targets that developed most recently in phylogeny are of particular functional value, and that the mesocorticolimbic dopaminergic system is involved in more complex integrative functions than previously assumed. In the present paper I will argue that some mental disorders may have their deep roots in the evolutionary mismatch between the normal physiology of the mesocorticolimbic dopaminergic system and the current environmental conditions in affluent societies. *Molecular Psychiatry* (2000) **5,** 467–475.

Keywords: evolution; limbic system; dopamine; stress; depression; emotions; Darwinian medicine

Introduction

The essential steps in the evolution of the brain from early mammals[1] to humans[2] show an increasing motor[3] and cognitive-emotional interaction[4] with the external world (Table 1). This 'environmental pressure' required the development of a neuronal system which was able to decipher and cope with the signals and stimuli coming from the brain's surroundings.

In this sense, the utilization of 'the principle of reward'[5] by linking outcomes of behaviors to either reinforcing or aversing sensations (and memorizing them), which is part of the normal physiology of the dopaminergic system, was absolutely instrumental in the course of evolution.

Several authors, however, consider such a view an over-simplification of the role of the mesolimbic and mesocortical dopamine circuits, which not only direct finalized movement in both animals and humans, but also motivate and coordinate the functions of higher brain areas that mediate planning, foresight and promote states of eagerness.[6,7] By these functions animals become intensely interested in exploring the world around them, but by the same means they are exposed and susceptible to the environmental stimuli that have been sought and consumed. In mammals, and especially in primates, the mesocortical dopaminergic

Correspondence: Dr L Pani, CNR Center for Neuropharmacology, Via Porcell, 4, 09124-I, Cagliari, Italy. E-mail: panil@unica.it
Received 3 January 2000; revised and accepted 10 April 2000

system generates and sustains curiosity, and it is quite efficient at facilitating learning. It is particularly effective in memorizing information about where material resources are located and the best way to obtain the things needed for survival, including food, water, warmth and sex.[8]

While telencephalic dopaminergic nuclei, such as the nucleus accumbens and the caudate-putamen, have been conserved in their gross and microscopic structure throughout evolution from rodents[9] to humans,[10] the structural organization of the cortical dopaminergic circuits, most strictly involved in human pathologies such as depression and psychosis, shows significant differences between rodents and primates.[11,12]

Recent data show that the major development of the cerebral cortex in primates was accompanied (or produced?) by a similar expansion of the dopaminergic input to all cortical layers, with a specific and laminar redistribution of the dopaminergic terminals.[11] It has been speculated that the cortical dopamine targets that developed most recently in phylogeny are to be considered of particular functional value, and that the mesocorticolimbic dopaminergic system is involved in more complex integrative functions than previously assumed.

In the present paper I will argue that the evolved physiology of the mesocorticolimbic dopaminergic system may be mismatched with respect to current environmental conditions and may contribute to the precipitation of human psychiatric disorders.

Evolution of the dopaminergic system

Enzymes

The acquisition of the behaviors modulated by dopaminergic innervation has been so indispensable in survival that the enzymatic machinery needed to synthesize dopamine appeared very early in phylogenesis. One of the most rudimentary nervous systems, that of the sea pansy *Renilla koellikeri (Cnidaria)*, is able to synthesize dopamine; such synthesis is inhibited by alpha-methyl-p-tyrosine.[13] In this invertebrate, the role of dopamine is that of giving bioluminescence and producing muscular contractions, which are most likely to be used to capture food or avoid danger; insufficient to result in such superior animal characteristics as the ability to feel pleasure and pain. The neurochemical basis of the effects of dopamino-mimetic drugs in other distant organisms has not been fully elucidated, but the hyperkinesia induced by cocaine, a drug which blocks the dopamine transporter, in Planaria specimens suggests that the selective site for pre-synaptic dopamine re-uptake is already present in this flatworm.[14] Goldfish show place preference for the water bowls where they have received amphetamine, a drug of abuse that increases dopaminergic transmission.[15] In the cephalochordate amphioxus, a sister group to vertebrates, the presence of dopamine (but not of noradrenaline) has been assayed. In contrast, two distinct genes homologous to the jawed vertebrate dopamine D1 and beta adrenergic receptor genes were shown to be extant in representatives of the earliest craniates, lamprey and hagfish, paralleling a high dopamine and noradrenaline content throughout their brain.[16]

Receptor family

The evolving vertebrate nervous system was always accompanied by major gene duplication events which generated novel organs along with a definite sympathetic system which was needed to monitor and control them. Vertebrate neural pathways synthesizing monoamine neurotransmitters (mostly dopamine and noradrenaline) were subsequently recruited in order to process increased information demands by mediating psychomotor functions, such as selective attention/predictive reward and emotional drive, via the activation of multiple G-protein linked catecholamine receptor subtypes.

At least 1000 million years ago (MYA), all the classical transmitter ligand molecules evolved the ability to activate a wide range of ion channels, resulting in excitation, inhibition and biphasic or multiphasic responses. In this respect, the invertebrate receptors which have so far been cloned show striking homologies with mammalian receptors, indicating that many of the basic receptor subtypes evolved at an early period, probably around 800 MYA.[17]

The evolution of these receptor-mediated events was similarly driven by forces of gene duplication, at the cephalochordate/vertebrate transition. In amphioxus, a single catecholamine receptor gene was found which, based on molecular phylogeny and functional analysis, forms a monophyletic group with both vertebrate dopamine D1 and beta adrenergic receptor classes.[18] These data suggest that a dopamine D1/beta receptor gene duplication was required for the elaboration of novel catecholamine psychomotor adaptive responses, and that a noradrenergic system specifically emerged at the origin of vertebrate evolution. Recent investigations have confirmed that the dopamine D1A, D1B, and D1C receptors share molecular, pharmacological, and functional attributes that unambiguously allow for their evolutionary classification as distinct D1 receptor subtypes of the G-protein linked super-family, in the vertebrate phylum.[18]

All these receptors conserve a fairly stable secondary structure, a moderate and reasonably steady rate of sequence change, and usually lack introns within their coding sequence. Several results indicate that the first event to occur within this gene family was the divergence of the catecholamine receptors from the muscarinic acetylcholine receptors, which occurred prior to the divergence of the arthropod and vertebrate lineages. Subsequently, the ability to activate specific second-messenger pathways diverged independently in both the muscarinic and the catecholamine receptors. This appears to have occurred after the divergence of the arthropod and vertebrate lineages, but before the divergence of the avian and mammalian lineages. However, the second-messenger pathways activated by adrenergic and dopamine receptors did not diverge independently. Rather, the ability of the catecholamine

receptors to bind to specific ligands, such as epinephrine, norepinephrine, dopamine, or octopamine, was repeatedly modified in evolutionary history, and in some cases was modified after the divergence of the second-messenger pathways.[19]

When the distribution of the dopamine D1 and D2 receptors in the brain of a mouse, rat, or cat is compared with that of a monkey, similarities are found only in the basal ganglia; the highest density being present in the caudate-putamen, in the nucleus accumbens, in the olfactory tubercle, and in the substantia nigra. Apart from these nuclei, and particularly in more recent structures such as the cerebellum and the frontal cortex, the absolute and relative values of the dopamine receptor subtypes is completely different in primates, suggesting that the transcriptional control of the gene encoding for the dopaminergic receptors has also undergone profound changes throughout evolution.[20]

The dopaminergic system and the mismatch theory

Large sets of data (for a review see Nesse and Williams)[21] have recently allowed the definition of a field theory called 'evolutionary mismatch', which derives its attributes largely from the fact that current environmental conditions in industrialized countries are completely different from those in which the human central nervous system evolved. The mismatch between evolved traits and contemporary lifestyle, the presence of evolutionary trade-offs (eg selection of some traits over others), and historical constraints (eg how a trait has evolved), has resulted in the poor specialization of selected traits, as well as a particular susceptibility to mental disorders.

To explain the somatic correlates of such an evolutionary view of diseases, it is assumed that pathogens that attack humans evolve faster than we do. If the ever-mutating environmental conditions, where change is mostly due to fast technological advancement (Table 2), could now be assimilated to organic pathogens, their rapid rate of evolution and change would impose a pressure that is not paralleled by an evolution of the brain structures which are able to analyze, process, and elaborate on such rapid variations. For example, a poor fit between strongly evolved traits (eg dependency) and the current urban social environment may account for the increase in frequency of anxiety and depressive disorders in modern societies.[22]

Current views on the evolutionary mismatch theory lack, however, a definition of which brain areas or neuronal circuits should be involved in coding such misevolved traits, and to what extent our neurobiological knowledge can be applied to the topographical localization of a specific psychopathology.

The appetitive and consummatory phases of behaviors triggered by environmental cues which are associated with survival properties (whether rewarding or aversive for the individual) are known to be mediated by sensory-specific dopaminergic neuronal circuits. These dopaminergic systems are involved in those mechanisms which determine satiety to food,[23] sex,[24] and drugs of abuse.[25] In all these conditions, the most important dopamine systems involved are that of the terminal fields of the prefrontal cortex,[26] and that of the nucleus accumbens,[27] both originating from neurons located in the ventral tegmental area of the midbrain. Whether the stimulation of these neurons mediates the incentive salience (reviewed in Berridge and Robinson),[28] or the associative learning[29] capacities of an event, is still a matter of intense debate. According to the first hypothesis, rewarding (and thus also averse) stimuli that have acquired motivational significance (salience) are part of a phenomenon which is neither unitary nor subjective; dopamine-related neural circuits mediating only a specific component of reward, ie the attribution of incentive salience to an otherwise neutral event. In contrast, others have argued that mesolimbic dopaminergic pathways do not code for such an ability, but serve only to respond to specific stimuli which possess high motivational impact, as a result of their novelty, unpredictability, specific sensory modalities, or occurrence under a deprivation state;[29] in these conditions, dopamine neurons define the substrate for precise associative learning abilities.

From an evolutionary perspective, the two mechanisms must play an equally important role in the attribution of an incentive value to ethologically relevant stimuli, and must facilitate, by means of both incentive-salience and associative-learning, the selection and the memory of appropriate behavioral responses. The conservation of such principles throughout evolution explains why pharmacological manipulations of the dopaminergic transmission are similarly able to modify basic behaviors in distant species such as lizards and rats (Table 3). Stimulation of the dopaminergic transmission will increase these behaviors, while the blocking of dopaminergic receptors or lesions of the dopaminergic pathways will decrease them. This confirms that dopamine is an

important neurotransmitter coding for sensory-specific responses, in the sense that a perceived environmental clue is acted on cognitively, either with an increase in exploration (by means of curiosity and reward) or a decrease (through fear and aversion),[30] but also show that the physiological responses of the dopaminergic system are strictly 'environment sensitive'. Electrophysiological recordings have indicated that key cortical and subcortical dopaminergic regions are involved in these motivated behaviors. Among these, a particular role in primates is given to the connections between the nucleus accumbens and the frontal cortex,[31] which I will consider as primary sites for the evolutionary mismatch between the dopaminergic system and the ability to process significant environmental-driven change-related information that guides coherent behavioral responses.

Expansion and regression of dopaminergic innervation

Animals with big brains are scarce, because bigger neuronal structures are more costly in terms of energy expenditure, development time, and anatomical complexity. It was always supposed that a much better diet (in terms of caloric value) must have been the starting point for the development of a much larger cerebral mass. Recently it was described how, about 40 MYA, a duplication of the gene coding for a retinal cone pigment in an ancestor of prosimians resulted in the development of trichromatic vision.[32] This ability to see in color was instrumental in detecting ripe fruit, and gave an immediate evolutionary advantage over green-leaf eaters. At about the same time, the system for emotional communication via facial expression expanded and the olfactory bulb completed its regression in primates.

Recently, this hypothesis was confirmed, showing that a highly predictable relationship exists between the relative size of the neocortex and that of the total brain.[33] When the sizes of 10 measured brain divisions from 131 species are plotted as a function of total brain size, the two most expanded structures in all species are, in fact, the neocortex and the striatum (caudate-putamen; nucleus accumbens and internal capsule), at variance with that of the olfactory bulb. Thus, two heavily innervated dopaminergic structures—one coupled to taste related reward and satiety, and the other to olfactory satiety—seemed to be mutually exclusive in their development. These complementary characteristics have been conserved in modern humans.[34] The neural mechanisms of sensory-specific satiety in primates are implemented in the orbitofrontal cortex, which has an important integrative function. Neurons in this region of the cortex were indeed found to respond to stimulation of the taste, olfactory, or visual systems. In addition, some neurons were found to possess a bimodal response; responding, for example, to both taste and olfactory, or taste and visual stimuli. Since these multimodal neurons were found in very close proximity to unimodal neurons, and since the unimodal sensory neurons were intermingled, it is possible that the orbitofrontal cortex represents the first cortical area of convergence for these three modalities in primates.[35]

Conditions that have changed through evolution and which interfere with the function of the dopaminergic system

Empirical data suggest a causal relationship between evolutionary-new environmental factors, specific dysregulation of the physiological ability of the dopaminergic system to process environmental stimuli and specific psychiatric disorders. Accordingly, the use of psychotropic medication in outpatient medical practice rose dramatically during the last 10 years, especially in industrialized countries.

Around 10 years ago, Gershon *et al* showed that the rates of bipolar, schizoaffective, and unipolar disorders were higher in the cohorts born after 1940 than in the cohorts born earlier.[36] It was suggested that an ominous trend could be present, leading to an increase in prevalence of a broad spectrum of familial affective disorders in the coming decades. This prediction proved to be correct and confirmed by more recent reports where changes in the prescribing patterns of psychotropic medications by office-based United-States physicians were examined.[37] In the 9 years period between 1985 and 1994, the number of visits during which a psychotropic medication was prescribed increased from 32.73 million to 45.64 million. Antianxiety or hypnotic drug visits, previously the largest category, decreased and were surpassed by antidepressant visits, which doubled from 10 to 20 million in the last 5 years period; and stimulant drug visits increased more than fivefold in the same period. These dramatic trends are in agreement with our findings (Table 4), where we consider the Italian sales of psychotropic medications classified into three major categories: anxiolytics, antidepressants, and antipsychotics and confirmed a significant tendency toward increase for antidepressants (+34%) and antipsychotics (+15%) but not for anxiolytics (+4%) in the last 5 years.

Thus, it appears that in current affluent societies the

Table 4 The Italian market for psychotropic compounds

	Millions of prescriptions per year

frequency of psychiatric disorders requiring medications which modulate the function of (and not only of) the dopaminergic system is increasing. In addition, the outcomes of acute affective disorders are considerably more favorable in developing countries than in comparable studies in developed settings[38] where at least four areas of evolutionary novelty can contribute and will be briefly discussed below.

Drugs of abuse

The ability to extract, purify and lately synthesize psychoactive compounds has increased their availability to the general population in quantities and qualities never experienced before in the history of mankind. In addition, the development of new routes of administration (eg hypodermic needles, crack smoking, organic solvents) has increased the penetration of drugs of abuse into the brain, and has contributed to a change in the traditional relationship between the use of the natural source of the drug (eg the chewing of cocaleaves) to that of its active component (eg the endovenous injection of cocaine hydrochloride).

Drugs of abuse offer a remarkable example of evolutionary mismatch at the level of the dopaminergic system, and help to clarify its role in the general physiology of the central nervous system. If drugs of abuse that act on the dopaminergic system (that is all of them, directly or indirectly) were used solely for their hedonic and 'reward producing' potential, then this capacity, ie the pure ability to experience pleasure, would be the only one to be mainly affected by their chronic use. Instead, after a variable period of use, all drugs which determine a state of dependence interfere with the global adaptation of an individual to its environment, producing not only an impairment of his/her hedonic capacities, but also a more disruptive effect on the cognitive and emotional abilities that are necessary for an effective interaction with the external world (maladaptation). The limbic portion of the dopaminergic system is essential for the generation of the basic emotions that mediate various pro-social behaviors, such as maternal care, playfulness, and friendship, and which have been learned and have evolved to influence motivational states and, ultimately, to increase fitness. All these behaviors, along with the emotions which are related to them and their cognitive implications, are profoundly altered in a drug addict, much more than just the capacity to experience pleasure or avoid pain (whether physical or psychological). Drugs of abuse that convey a signal that falsely indicates the arrival of a huge fitness benefit (much higher than food, water, sex, etc), actively change behavioral hierarchies. As a consequence, drug-seeking increases in frequency to the point where it becomes the only dominant behavior, displacing all the other adaptive traits.[39]

Stress

The definition of the term stress has gone from 'a nonspecific response of the body to any demands made upon it',[40] to 'both a survival mechanism and an indicator of internal and external cues'.[41] Both acute and chronic stress have a detrimental impact on the normal function of the dopaminergic system (for a recent review see Pani *et al*).[42] The response of the dopaminergic system to stress is neither homogenous nor generalized, and numerous results suggest that mesoprefrontal cortex dopaminergic projections are selectively activated by sudden changes in environmental conditions, whether expected or not.[43]

The fine tuning of dopamine extracellular concentration in the medial prefrontal cortex seems to be essential for the decision-taking protocols of the medial prefrontal cortex in the rat and the monkey.[44] This supports the idea of a critical range of dopamine turnover for optimal prefrontal cortical cognitive functioning, with reduced or excessive dopamine turnover leading to cognitive impairment. Several data point to ventral tegmental area projections,[45] dopamine receptors,[46] and a loss of inhibitory tone on ventral tegmental area dopamine cells[47] and lateral-basolateral amygdala (see below) as important regulatory sites for maintaining superior cognitive functions. The increased ability to remove dopamine in chronically stressed animals has also indicated that altered dopamine clearance may serve as an adaptive mechanism in the medial prefrontal cortex.[48] It has been further suggested that increased dopamine D1 receptor stimulation during stress may serve to take the medial prefrontal cortex 'off-line', in order to allow posterior cortical and subcortical structures to regulate more 'primitive' forms of behavior.[49] Since dopaminergic innervation of the medial prefrontal cortex is able to regulate the activity of subcortical dopamine innervations, disruption of the medial prefrontal cortex dopamine fibers may result in the altered biochemical responsiveness of the dopamine subcortical innervations.[50]

In humans, the balance between cortical and subcortical dopaminergic activity may serve as a protection against psychotic decompensation from chronic endogenous or exogenous insult,[51] and the failure of this coping mechanism may well contribute to the vulnerability of the medial prefrontal cortex in many neuropsychiatric disorders related to the stress response.[52]

Chronic emotional reactions

Emotional responses can be difficult to differentiate from generic reactions to stress, in laboratory animals as well as in humans. In addition, emotions such as

empathy seem to be uniquely human, and therefore impossible to mimic in animal models. In spite of this, several animal behaviors such as freezing, self-grooming, exploration and defecation have been considered as valid somatic correlates to human emotional responses in which the dopaminergic system is involved. In all the models, the chronic nature of the stimulus is essential to produce a stable change in the normal physiology of the dopaminergic system. In modern times this can be obtained by generic stress due to sleep disruption, time shifts, poor physical activity, increased physical constraints, and unnatural social rules. In diseases in which dopamine function is compromised, humans exhibit a constellation of emotional symptoms, suggesting that the dopamine system plays an important role in the integration of superior cortical functions. A dorsal tier of dopamine neurons receives input from the nucleus accumbens and from the amygdala, and projects widely throughout the cortex. Through these projections, the dopaminergic limbic system has an enormous influence on cortical output and can therefore affect the emotional and motivational 'coloring' of a wide range of behaviors.[53]

In this respect, the lateral-basolateral amygdala receives sensory input from environmental stimuli and, along with the central amygdala, mediates conditional fear. Through its projections to forebrain, midbrain and hindbrain areas, the central amygdala governs the behavioral, autonomic, and endocrine responses that characterize a central fear state.[54] Accumulating revelations about the amygdala-based fear system has led to considerable progress in delineating the neural connections and cellular mechanisms that underlie aversive emotionality, and very recently electrophysiological evidence has shown that neural discharge in the central amygdala is a consequence of repeated low-current, high-frequency electrical stimulation of dopaminergic nuclei of the ventral tegmental area.[55]

The introduction of Roman high-avoidance (RHA) and Roman low-avoidance (RLA) rats, two selectively bred lines that differ in their level of emotionality, into an unfamiliar environment, the application of a high-intensity loud noise, or immobilization, are all associated with an increase in extracellular cortical dopamine metabolite levels in the RHA but not in the RLA line, suggesting that the differently evoked emotional reactions may produce a common activation of cognitive processes.[56] This difference in reaction to a stressful stimulus, according to the genetic makeup of an individual, is an essential function of the mesencephalic dopaminergic neurons, and of their role in the organization of behavioral responses which are the reflection of a heightened attention of the animal attempting to cope with the stressor.[57] The mesocortical dopaminergic innervations seem to facilitate the functions of integrative structures, and to have a coordinated role in regulating the information flow between cortical structures.[58]

The study of fear and the role of the dopaminergic system in rodents have, however, produced inconsistent data. While some results suggest an important relationship between social and motor reactivity, as well as an important, albeit again strain-dependent, role for dopamine D1 receptors in mediating specific emotional behaviors,[59] others demonstrate that long-term administration of low, pre-synaptic doses of the dopamine D2 antagonist l-sulpiride is highly effective in an animal model of anticipatory anxiety/panic behavior.[60] In contrast, recent findings suggest that quinpirole (a dopamine D2 agonist) decreases fear by blocking the retrieval of a learned association between a conditioned and an unconditioned stimulus.[61]

Chronic sleep deprivation

Humans have conserved mechanisms, like those that exist in other animals, which detect changes in day length and make corresponding adjustments in the duration of nocturnal periods. Several studies from Wehr and collaborators[62] have suggested that modern men's use of artificial light after dark and artificial darkness during the daytime suppresses responses[63] to seasonal changes in the duration of the natural scoto- and photoperiod that might otherwise occur at a given latitude, producing a chronic disturbance in the sleep pattern and decreasing, overall, the total amount of sleep. It is difficult to conceive that chronic sleep deprivation in humans could be obtained and maintained without any activation in the stress axis.

Sleep deprivation in rats has been extensively studied as a possible animal model of mania.[64] Interestingly, at the end of the period of sleep deprivation (approximately 72 h), the rat does not fall asleep as soon as it is returned to its home cage, but shows a period of wakefulness of about 30 min, during which the animal presents a cohort of symptoms that appear to mimic those present in idiopathic mania. In particular, during this period the animal displays a high degree of hyperactivity, irritability, aggressiveness, hyper-sexuality, and stereotypy. The model allowed the discovery of an active role of limbic dopamine in the generation of arousal and insomnia related to sleep deprivation-induced stress.[65] Accordingly, direct evidence demonstrates that acute and chronic sleep deprivation may trigger a manic episode in otherwise healthy individuals,[66] and that recurrent brief hypomania which lasts 1–3 days and belongs to the bipolar spectrum, is increasing in young adults.[67] These findings are indirectly confirmed by the increased use of neuroleptics (Table 4) which, although their use has been widely discouraged for mood disorders, are still the standard treatment for acute bipolar mania.[68]

Conclusions

The brain of *Homo sapiens sapiens* developed on the African plains, in populations of a few hundred thousand individuals; today there are six billion of us worldwide.

It is time to ask ourselves whether the structural organization and the neuronal plasticity of the human

brain are still able to control the evolution of the environment he has created. Some influential neurobiologists have expressed strong doubts.[69]

The dopaminergic innervation to the prefrontal cortex is essential for processing and elaborating on the 'expectancy' of events, and in the working memory related to them, in both rats and monkeys.[44] Environmentally induced changes in the activity of the dopaminergic system, either by conventional (food, water, sex etc) or non-conventional (drugs of abuse, chronic stress, emotional reactions etc) stimuli could mismatch the natural codes for reward-aversion, sensory-motor, incentive-salience mechanisms which have been conserved in the last millions of years and which are needed to associate a learned outcome of a given stimuli with a definite emotional state of the organism.

In this sense, the dorsolateral portion of the prefrontal cortex is important in monitoring the context of the situation in relation to how, and what, reward is given.[70] Patients with prefrontal lesion are poor in assessing how actions relate to goals. The results suggest that pre-frontal cortical lesions provoke a selective impairment in managerial knowledge that may contribute to difficulties in the formulation and execution of plans.[71]

Neurons which are critical for the computation of sensory-specific satiety in the monkey are located in the orbitofrontal cortex and, in humans, decision-making processes depend on signals arising in the prefrontal cortex in association with peripheral somato-visceral signals that can introduce biases in the reasoning processes.[72] When normal subjects experience situations that they associate with the possibility of negative consequences, they sense a peripheral reaction (mainly an adrenergic response) and learn to make decisions accordingly. Damage to the orbitofrontal cortex in adulthood as well as in early life[73] disrupts the capacity to make these physiological responses, and impairs this ability to make crucial social decisions.

Considering the profound influence of prefrontal cortex damage on several adaptive behaviors in rats and primates, another question arises: is it possible that in the absence of organic pathologies, a 'functional uncoupling' of the cognitive capacities (eg working memory, decision-making, associative learning) of the prefrontal cortex could be the site of the dopaminergic evolutionary mismatch?

In this respect, the temperament (as the genetic model of personality)[74] of an individual may strongly relate to this evolutionary model. If this theory holds true it should be possible to study by imaging techniques whether or not patients with different temperaments, obviously selected by natural selection for conferring evolutionary trade-off, such as the bipolar-anxious temperament types,[75,76] would show any difference in the functions of their prefrontal cortex activity.

A better understanding of the mechanisms, origins and functions of the dopaminergic system as well as other neurotransmitters and modulators, will also enhance our ability to cope with stress-related mental disorders in the modern environment, and sharpen our wisdom in making decisions about the therapeutic use of psychoactive drugs.

Eyes, More Than Other Facial Features, Enhance Real-World Donation Behavior

Abstract

Humans often behave more prosocially when being observed in person and even in response to subtle eye cues, purportedly to manage their reputation. Previous research on this phenomenon has employed the "watching eyes paradigm," in which adults displayed greater prosocial behavior in the presence of images of eyes versus inanimate objects. However, the robustness of the effect of eyes on prosocial behavior has recently been called into question. Therefore, the first goal of the present study was to attempt to replicate this effect. Additionally, it remains unclear whether the watching-eyes effect is driven specifically by reputation management (owing to the monitoring function of the eyes) or whether any cues indexing human presence more generally also have a similar effect. To address these questions, the current study compared prosocial behavior in the presence of eyes versus inanimate objects as well as other human features. The study was conducted as a field experiment at a children's museum. Each week, the donation signs were changed to show eyes, noses, mouths, or chairs. Total donation amount and number of patrons per week were recorded. Participants donated more when they were exposed to eyes than to inanimate objects (chairs). We thus replicated the previously reported watching-eyes effect. Moreover, more money was donated when individuals were exposed to eyes than to more general cues of human presence (nose and mouth). The current findings suggest that eyes play a special role in promoting cooperation in humans, likely by serving as cues of monitoring and thus eliciting reputation management behavior.

Humans are highly cooperative beings who willingly offer resources to non-kin on a daily basis (Hare 2017). This high level of generosity is maintained in part by reputational forces—through both the gains incurred when individuals are seen carrying out positive actions and the costs incurred when individuals are seen breaking cooperative norms (Fehr and Gächter 2002; Milinski et al. 2002; Wedekind and Milinski 2000). As a result of these reputational forces, people often engage in reputation management (or "self-presentation"; Goffman 1959) by behaving more prosocially when being watched by others (e.g., Bull and Gibson-Robinson 1981; Kurzban 2001). Indeed, even children as young as 5 years of age are more generous and less antisocial in the presence of others (Engelmann et al. 2012; Leimgruber et al. 2012).

It is argued that reputation management does not rely solely on explicit or conscious reasoning; rather, because managing one's reputation has been so vital for the evolution of human cooperation, natural selection has shaped human psychology to also be sensitive to even minimal cues of being observed (Haley and Fessler 2005). This "watching-eyes" effect is supported by numerous studies. For example, several studies using one-shot anonymous dictator games found that donations (either the proportion of individuals who donated, the average donation amount, or both) were greater from participants exposed to images of eyes than to non-social stimuli (e.g., geometric shapes; Haley and Fessler 2005; Keller and Pfattheicher 2011; Nettle et al. 2013; Oda et al. 2011). In field experiments, the presence of eyes compared with non-social controls has been found, for instance, to increase removal of litter, increase voter turnout, and reduce bicycle theft (Bateson et al. 2013; Burnham and Hare 2007; Ekström 2012; Ernest-Jones et al. 2011; Nettle et al. 2012; Panagopoulos 2014a, b).

However, several studies—from both the laboratory and the field—have failed to find support for the watching-eyes effect (Carbon and Hesslinger 2011; Fehr and Schneider 2010; Manesi and Pollet 2017; Saunders et al. 2016; Sparks and Barclay 2015). In addition, the effect is often apparent only under certain conditions and using certain measures. For instance, one meta-analysis of 25 studies found that increased generosity emerges after short exposure to images of eyes (i.e., when eye cues are made suddenly visible or attention is drawn to them in the seconds before the dependent measure is recorded), but not after long exposures (i.e., when eye cues are available for several minutes prior to when the dependent measure is recorded; Sparks and Barclay 2013). Note, however, that this meta-analysis used a vote-counting technique: It included any study that found either an increase in the proportion of individuals who donated or an increase in donation amount after exposure to eye cues as providing support for the effect. Specifically, studies that reported a significant effect with one measure, but not another measure, were nonetheless included as a vote for the effect, which may have made the effect appear more robust than it is. Another meta-analysis (Nettle et al. 2013) suggested that the watching-eyes effect is not generally apparent in the amount that people donate but rather whether people donate anything at all, and the most recent meta-analysis revealed no evidence that cues of observability increase the proportion of individuals who engage in prosocial behavior or the total amount of prosocial behavior (Northover et al. 2017). Given the mixed evidence on the watching-eyes effect, and given the importance of replicability of experimental work (Nosek et al. 2015), the first goal of the present study was to attempt to replicate the watching-eyes effect. Toward this end, we compared people's generosity in the presence of an image of eyes versus an image of a nonsocial stimulus (a chair).

Importantly, even when the watching-eyes effect does emerge, it remains unclear whether it is indeed driven by reputation management. Typically, studies on this topic have compared the effect of eyes (or eye-like images) with that of images of non-social objects (e.g., flowers or geometric shapes). In these comparisons, greater prosociality in the presence of eyes is taken as evidence that individuals exposed to the eyes feel that they are being observed and thus act in ways that will maintain or enhance their reputations (Bateson et al. 2006; Haley and Fessler 2005). It is thus assumed that it is the monitoring (or reputation-forming) function of eyes that elicits greater prosociality. An alternative possibility, however, is that eyes serve as a more general cue to human presence, and that other general cues of human presence (such as other facial features) could also increase people's prosocial behavior through various possible means, such as by making them feel more social, reminding them that they are part of a group, reminding them that there are people in need, alerting them to the possibility of being punished or sanctioned, and so on. In other words, the mechanism underlying the watching-eyes effect might not be reputation management but rather more general effects of social presence. If this latter argument is correct, then the eyes may not be unique in increasing generosity; rather, any cue of human presence may result in this effect. In contrast, if the watching-eyes effect is at least partially explained by reputation management, then eyes should be especially effective in increasing prosocial behavior, as the eyes are unique among the human features in their "watching" function and are therefore an especially relevant cue for reputation management (see Manesi et al. 2016; Vaish et al. 2017). The second goal of this study was thus to test whether eye cues in particular or cues of human presence more generally enhance prosocial behavior.

Although no prior work has directly tested this question, a few studies have attempted to clarify the mechanisms underpinning the watching-eyes effect. Eyes are highly salient cues, and from birth, humans preferentially attend to eyes (for a review, see Grossmann 2017). This privileged attention to eye cues is seen in newborns' preferences for eye-like stimuli (e.g., configurations of three dots that resemble a face with eyes) and in newborns' preferences for faces with direct gaze as opposed to averted gaze (Farroni et al. 2002, 2005). This preferential sensitivity to eyes continues to exist into adulthood, as adults prefer to look at eyes more than at other body parts (Vaish et al. 2017). Eyes, and especially watching eyes, are thus highly salient cues.

Regarding the watching effect in particular, of most relevance are three experiments in which Manesi and colleagues (Manesi et al. 2016) examined whether adults exposed to "watching" eyes (i.e., eyes with direct gaze) were more likely to help others with a dull cognitive task than individuals exposed to closed or averted eyes and to a non-social control (flowers). The findings across the three experiments were inconsistent: There was evidence for increased helping after exposure to watching eyes under certain conditions (e.g., for open eyes compared with closed eyes, and direct gaze compared with a head turned away) but not under other conditions (e.g., direct gaze versus averted gaze without a head turn). When the results from the three experiments were analyzed together, there was some evidence that participants were more generous in the presence of watching eyes than the other stimuli. Manesi et al. (2016) tentatively concluded that it is the monitoring function of the eyes that increases prosocial behavior and that the mechanism behind the watching-eyes effect is thus reputation management. In line with this conclusion, other work shows that the impact of eye cues on donation behavior is mediated by how much individuals expect their donation behavior

to be evaluated by others and by the expectation that donating more money will enhance their reputation (Oda et al. 2011). Additionally, studies on individual differences show that individuals with higher chronic public self-awareness (who are presumably more concerned about their reputations) are more generous in the presence of watching eyes than individuals who are lower on this trait (Keller and Pfattheicher 2011), and individuals who attend more to eyes (but not to other human features) are more generous, but only when donating publicly (i.e., when their reputation is at stake), not when donating privately (Vaish et al. 2017). This body of work provides some support for the reputation management explanation.

Moreover, recent work has examined how donation amounts given in a dictator game differ after exposure to eyes when compared with other social cues. One study reported that individuals exposed to eyes (photos portraying only the eye regions of statues) donated significantly more money than individuals in a more general social condition (pictures of peers not directly facing the participant) or in a non-social control condition (pictures of school hallways; Baillon et al. 2013). Similarly, Haley and Fessler (2005) examined whether another sign of human presence—auditory cues—influenced donation behavior. They found that adults who wore noise-reducing headphones (and thus received fewer auditory cues of human presence) donated just as much as those who did not wear headphones, suggesting that eyes are perhaps especially effective at eliciting reputational concerns.

Nonetheless, given the mixed findings from Manesi et al.'s (2016) experiments and the fact that no prior work has assessed the effect of other human features on generosity in a real-world setting, we aimed here to further investigate the reputation management explanation of the watching-eyes effect using a novel approach. Specifically, we compared donation behavior in the presence of eyes to that of other human features in order to directly test whether eyes play a special role in enhancing prosocial behavior through eliciting reputational concern. We reasoned that if the presence of eyes increases prosocial behavior by eliciting reputational concerns, then the eyes should be especially effective in increasing prosocial behavior as compared with other human features. On the other hand, if eyes increase prosocial behavior merely by cueing human presence, then other human features should be similarly effective in increasing prosocial behavior. The two other human features we used were the nose and mouth. Like the eyes, they are inner features of the human face and are thus similar to the eyes in terms of their visibility to others but do not serve the visual monitoring function that eyes do.

Finally, to our knowledge, the prior studies using social control conditions were all conducted in laboratory settings (Baillon et al. 2013; Haley and Fessler 2005; Manesi et al. 2016); to examine the generalizability of the effects to a real-world setting, it is important to extend this line of research to the field. The present study was thus conducted as a field experiment. Specifically, the study was conducted in a children's museum. Each week, the donation signs were changed to feature images of eyes, noses, mouths, or chairs, and the total donation amounts and numbers of patrons were recorded. If the watching-eyes effect is replicable in this setting, then an image of eyes on the donation sign should yield higher donations than the non-social control condition (chair). Additionally, if it is indeed the monitoring function of the eyes that increases prosocial behavior, then eyes should elicit greater donations than other cues of human presence (mouth and nose).

Method

Setting and Participants

This study was conducted in a local children's museum in a small, mid-Atlantic university town in the United States. The museum caters to families with children up to 8 years of age. Overall, the demographics of visitors to the museum reflect those of the surrounding area. According to the US Census Bureau (2016), the median household income for the surrounding area is $49,775, the majority of residents are white (69.9% white; 19.0% black; 7.6% Asian; 3.5% other), and around half (49.8%) of the residents have obtained a college degree. During the 28 weeks in which data were collected, a total of 34,140 patrons (including adults and children) visited the museum and were exposed to the experimental manipulation of the donation box.

Procedure

The museum has a permanent, transparent donation box (without any accompanying images) with the sign "Donations would be appreciated" at the check-in desk at the front of the museum. Typically, patrons pay a price to enter the museum and in addition are welcome at any time to contribute to the donation box. All proceeds collected from the donation go toward the museum's general upkeep. For the purposes of this study, for a total of 28 weeks (between 2015 and 2017) the regular sign on the donation box was replaced by one of four signs that we provided the museum (pictures of the signs for all four conditions are provided in the ESM). These signs featured two 1 × 2-in. photographs of eyes, noses, mouths, or chairs. On any given sign, the two photographs showed different exemplars of the same item (e.g., one male and one female pair of eyes) above and below the phrase "Donations would be appreciated" (see Fig. 1 for an example from the Eyes condition). Pictures of the eyes, noses, and mouths were individually cropped from neutral-expression photos taken from the previously validated FACES database (Ebner et al. 2010). The pictures used in the chair condition were taken from the Bank of Standardized Stimuli (BOSS; Brodeur et al. 2014).

Once a week, the manager at the museum, who was blind to the hypotheses of the study, changed the donation sign according to a randomized order that we had provided, removed all of the donation money from the previous week to ensure that the donation box was empty at the start of each new week, and recorded the donation amount and number of patrons (adults and children). The donation box was located at its usual location at the check-in desk. Museum employees working at the check-in desk were unaware that the donation behavior and the experimental manipulation were being recorded. Data were not collected during weeks when donation behavior and attendance at the museum were subject to high flux, such as when a week included holidays on which the museum was closed (e.g., Thanksgiving and New Year's Day) or closures due to weather. Finally, over the course of the study, the museum underwent renovations for a period of 4 months. During this time, the museum was closed and no data were collected. To minimize any effects of the renovations on our data, we ensured that each condition was carried out a similar number of times before and after the renovations. A chi-square test confirmed that there were no significant differences in the frequency of each condition before and after the renovations ($p = .76$).

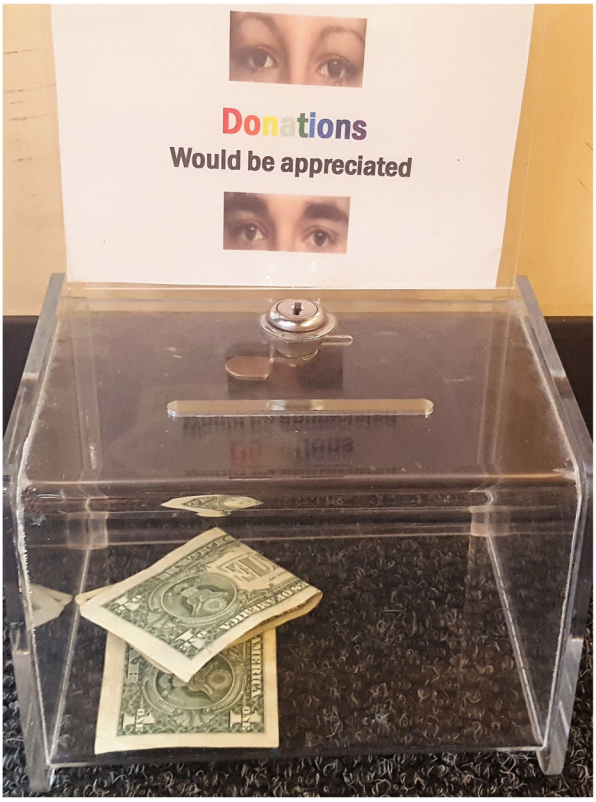

Fig. 1 Picture of the donation box with an example sign (from the Eyes condition)

Results

During the 28 weeks in which data were collected, the number of patrons who visited the museum per week (including adults and children) ranged from 533 to 1916 (M = 1219.29, SD = 406.24) and the total amount donated per week ranged from $3 to $46.33 ($M$ = $15.16, SD = $14.32). In order to account for the fluctuations in the number of patrons each week, we calculated the average amount of money donated per patron. An ANOVA with this average donation measure as the dependent variable and condition (Eyes, Nose, Mouth, Chair) as the independent variable revealed a significant effect of condition, $F_{3, 24} = 3.51$, $p = .031$, $\eta^2 = .31$ (Fig. 2).[1]

In relation to our first goal of replicating the watching-eyes effect, we compared the Eyes condition to the non-social (Chair) condition. A planned comparison using an independent samples t test indicated that the money donated per patron in the Eyes condition (M = .018, SD = .006) was significantly greater than in the Chair condition (M = .008, SD = .004), $t_{12} = 3.62$, $p = .004$, $d = 1.96$. We were thus able to replicate the basic watching-eyes effect.

[1] All of our results held when we used a one-way ANOVA with bootstrapping (10,000 replications) and performed post-hoc analyses with a Bonferroni correction.

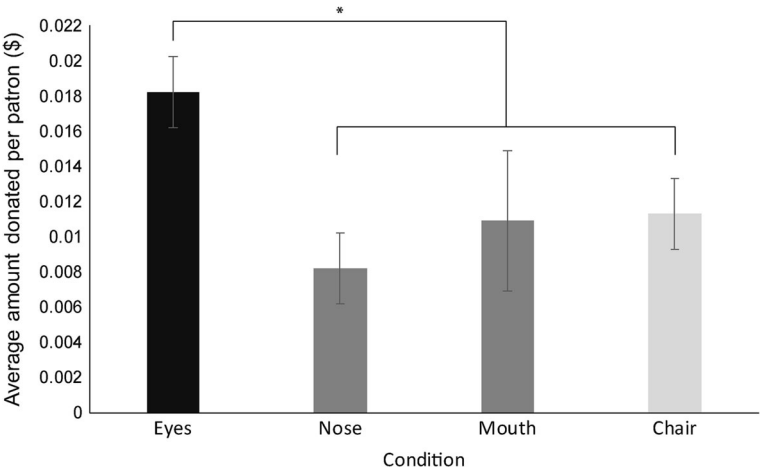

Fig. 2 The average amount of money donated per patron across conditions. Error bars indicate the standard error based on the total donation amounts for each week

In relation to our second goal of assessing whether the eyes increase donations more than other indicators of human presence, we pooled the two human-presence control conditions (Nose + Mouth, resulting in 14 weeks of data in total) and compared them with the Eyes condition. The donation per patron was greater in the Eyes condition ($M = .018$, $SD = .006$) than in the pooled human-presence control conditions ($M = .010$, $SD = .008$), $t_{19} = 2.55$, $p = .019$, $d = 1.13$.[2] When the Eyes condition was compared with each human-presence control condition separately, we found that the average amount donated per patron in the Eyes condition was greater than in the Nose condition ($M = .008$, $SD = .005$), $t_{12} = 3.29$, $p = .006$, $d = 1.81$. However, the average amount donated per patron in the Eyes condition was not significantly greater than in the Mouth condition ($M = .011$, $SD = .010$), $p = .13$.

Finally, exploratory analyses were conducted to examine the differences in donation behavior between the three control conditions (Nose, Mouth, Chair). There were no significant differences in donation behavior between the Nose condition and the Mouth condition, $p = .53$. In addition, donation behavior in the Chair condition did not significantly differ from either the Nose, $p = .90$, or the Mouth, $p = .47$, conditions.

Discussion

The current field study examined whether the presence of eyes enhances donation behavior more than a non-social cue and more than other social cues. By showing that participants exposed to eyes donated more than participants exposed to non-social visual cues (chair), the current study replicates previous research on the watching-eyes effect (Bateson et al. 2006; Haley and Fessler 2005). Our results further revealed greater donation behavior in response to the Eyes condition compared with other social

[2] This analysis had an unequal number of cells: 14 in Nose + Mouth pooled vs. 7 in the Eyes condition. We therefore also conducted a nonparametric test, which revealed a very similar result: Mann-Whitney U = 18.00, $p = .020$).

cues indexing human presence (Nose and Mouth conditions combined). The current findings therefore replicate and critically extend previous work and suggest that eyes play a special role in fostering cooperative behavior among humans. This is in line with the notion that cues to being watched result in reputation management behaviors (Bateson et al. 2006; Haley and Fessler 2005).

The watching-eyes effect has received a great deal of attention and has been demonstrated extensively (Bateson et al. 2006; Ernest-Jones et al. 2011; Haley and Fessler 2005). However, numerous recent studies, including meta-analyses, have failed to find strong support for the effect (Carbon and Hesslinger 2011; Fehr and Schneider 2010; Manesi and Pollet 2017; Northover et al. 2017; Saunders et al. 2016). We tested donation behavior in a real-world setting and were able to replicate the effect that watching eyes enhance prosocial behavior. Our results showed that the average donation amount per patron was greater in the presence of images of eyes than in a non-social control condition (images of chairs). Specifically, exposure to eyes yielded an average increase of $0.01 per patron compared with that of chairs. Although an increase of $0.01 per patron appears small, given the average number of museum patrons each week (more than 1200), this seemingly small difference amounts to an overall increase in donation of approximately $12 per week. Considering that the average donation amount per week (for the 28-week period) was about $15, a $12 increase is substantial and is more than what the results adjusted for patron number seem to suggest at first sight.

In light of conflicting reports in the literature, it is important to consider why the present study revealed an effect of watching eyes on prosocial behavior whereas some others have not. First, whereas some failed replications have employed stylized eyes (Fehr and Schneider 2010; Vogt et al. 2015), the eye stimuli in the present study were realistic photographs of human eyes, which might be more salient cues to being watched. Note, however, that prior studies using both stylized eyes (Haley and Fessler 2005; Vogt et al. 2015) and photographs of eyes (Bateson et al. 2006; Matsugasaki et al. 2015) have yielded mixed results. Thus, our use of photographs of eyes is unlikely to be the sole explanation for the discrepancy between our successful replication and prior non-replications.

Another possible explanation is based on findings indicating that context influences the amount donated in the presence of eye cues. In the present study, the donation box was located in the entrance area, which is typically busy with patrons checking in and leaving the museum, and a museum staff member was always present at the reception desk. These factors created a relatively public context for people's donations. The context is important because prior work indicates that attentiveness to eyes is predictive of donation behavior in a public (i.e., reputation-relevant) context but not when donation behavior is private or anonymous (Andreoni and Petrie 2004; Lamba and Mace 2010; Vaish et al. 2017). Accordingly, the public context in our study may have impacted and enhanced patrons' donation decisions, particularly in the presence of eyes. Moreover, since the donation box was transparent, patrons could see how much had already been donated, which might have resulted in participants inferring donation norms (see Fathi et al. 2014). This may have amplified the effect in the Eyes condition over the course of the week. Note, though, that this explanation has as its premise that more money was donated in the Eyes condition early in the week, which in turn provides support for the watching-eyes effect.

Finally, the positive result may be related to the fact that the current study was carried out in a real-world setting, in which, unlike in laboratory settings, participants do not know that they are part of an experiment. Indeed, positive results and larger effect sizes for watching eyes have been predominately obtained in field studies rather than in laboratory experiments. In fact, Northover et al. (2017), who did not find evidence for the watching-eyes effect, did not include some of the existing field studies in the first of two meta-analyses that they conducted—on the amount given after exposure to eyes (e.g., Ekström 2012; Powell et al. 2012). This indicates that there are contextual factors that may play a role in contributing to the watching-eyes effect. However, note that the second meta-analysis conducted by Northover et al. (2017)—on the proportion of participants who gave after exposure to eyes—did include some field studies (e.g., Ekström 2012), but still failed to find support for the watching-eyes effect. Clearly, more research is needed to determine whether and how contextual factors impact the watching-eyes effect.

The second goal of the present study was to better understand the mechanism underlying the watching-eyes effect. Prior work has generally assumed that the watching-eyes effect results from reputational concerns triggered by the monitoring function of the eyes (Bateson et al. 2006; Haley and Fessler 2005). However, an alternative possibility is that the eyes simply cue human presence, which increases prosociality for non-reputational reasons such as making individuals feel more social or part of a group, making them think about others' needs, or alerting them to possible sanctions for non-cooperation. In order to address this possibility, we compared the effect of eye cues on donation behavior with that of other human features (noses and mouths), which should similarly cue human presence. We reasoned that if reputational concern triggered by the monitoring function of the eyes is the key mechanism underlying the watching-eyes effect, then the eyes should be especially effective in enhancing donation behavior when compared with the other human features. In line with this, we found that patrons donated more money during weeks that featured the eyes than in the weeks that featured the other human features (Nose and Mouth pooled). These results are in agreement with prior (tentative) findings that watching eyes yield greater donations than closed eyes or eyes with an averted gaze (Manesi et al. 2016; see also Baillon et al. 2013). Together, these findings support the idea that the presence of eyes does not increase prosocial behavior simply by cueing social presence but rather through the monitoring function of the eyes, which enhances people's reputational concern and motivates them to engage in self-presentational behaviors.

One alternative to consider is that perhaps the eyes are more effective in cueing human presence than the other facial features. This is because when seen in isolation, they represent the most powerful trigger for face recognition processes (Keil 2009). In other words, eyes may be a sufficient feature to detect a face, whereas features such as noses and mouths may not by themselves be immediately recognized as faces and thus may not cue human presence as effectively. It will be informative for future work to examine how quickly and effectively the eyes versus other features are recognized as human stimuli and what impact this has on prosocial behavior.

We also explored potential differences in donation behavior between the Eyes condition and each individual human feature condition (Nose and Mouth) separately without specific a priori hypotheses for these comparisons. Donation behavior was significantly greater in the Eyes condition than the Nose condition but was not

significantly different between the Eyes and Mouth conditions. Importantly, donation behavior also did not significantly differ for the Mouth, Nose, and Chair conditions. The overall pattern with regard to the Mouth condition is difficult to interpret because no clear difference was obtained between the Mouth and any of the other conditions, leaving unclear whether the Mouth condition functioned more like the Eyes or more like the other control conditions (Nose and Chair). However, we might speculate that the mouth, which is critical for communicating with others and spreading information, might also be perceived as a (weaker) cue for reputation management and thus enhance donation behavior somewhat. These proposals are of course tentative and go beyond the conclusions that our data permit, but they raise interesting questions for future research.

In conclusion, the current study provides further empirical evidence that eyes enhance donation behavior in a real-life setting. Our results critically extend previous research by showing that viewing eyes selectively increases prosocial behavior, while viewing other cues that only indicate human presence does not have such an effect. These findings support accounts positing that eyes play a special role in fostering cooperative behaviors in humans, likely by eliciting reputation management.

Acknowledgments We are extremely grateful to the Virginia Discovery Museum in Charlottesville, VA, and in particular to Kaitlin Clear German for all her assistance with data collection. In addition, we would like to thank Janine Oostenbroek and Katie Krol for helpful discussions and comments on the manuscript.

Facing puberty: associations between pubertal development and neural responses to affective facial displays

William E. Moore III,[1] Jennifer H. Pfeifer,[1] Carrie L. Masten,[2] John C. Mazziotta,[3] Marco Iacoboni,[3,4] and Mirella Dapretto[3,4]

Adolescence is marked by profound psychosocial and physiological changes. Although investigations into the interactions between these forces have begun to shed light on the neural correlates of affective processing during the transition to adolescence, relatively little is known about the relationship between pubertal development and emotion perception at the neural level. In the current longitudinal study, 45 neurotypical participants were shown affective facial displays while undergoing fMRI, at ages 10 and 13. Neural responses to emotional expressions at both time points were then correlated with a self-report measure of pubertal development, revealing positive associations with activity in amygdala, thalamus and visual cortical areas at age 10 that increased in magnitude and extent by age 13. At the latter time point, pubertal development was additionally correlated with enhanced responses to faces in temporal pole, ventrolateral prefrontal cortex (PFC) and dorsomedial PFC. Longitudinal comparisons revealed that the relationships between pubertal development and activity in the amygdala, hippocampus and temporal pole were significantly stronger during early adolescence than late childhood. These results suggest that pubertal development per se is linked to neural processing of socioemotional stimuli, particularly with respect to the integration of complex perceptual input and higher order cortical processing of affective content.

Keywords: adolescence; puberty; emotion; fMRI; amygdala; longitudinal

Folk wisdom suggests that teenagers are ruled by their emotions, in part due to their 'raging hormones'. Teens also have to cope with considerable interpersonal changes, as relationships with peers take on a new level of importance (Larson and Richards, 1991; Brown, 2004). Together, these facts raise questions concerning not only the adolescent emotional experience, but also how teens perceive emotional states in others (Dahl and Gunnar, 2009). In light of the 'social reorientation of adolescence' (Nelson *et al.*, 2005), reacting appropriately to the feelings of peers is an important skill for the developing brain to hone. Of course, in addition to shifting social and emotional contexts, adolescence is also a period of significant physiological change. While outward manifestations that signal the end of childhood are often plain to see (e.g. increased height), the effects of puberty on brain function are by nature more elusive. It is important to determine how neural responses to key socioemotional stimuli, such as affective facial displays, are affected by pubertal development—distinct from chronological age.

Although it has been said that the science of adolescent brain development is itself at an age often associated with pubescent growing pains (Steinberg, 2010), the field is in many ways still in its infancy. The neural networks associated with perceiving and reacting to emotional expressions have been targets of neuroimaging research for more than a decade (Adolphs, 2002; Haxby *et al.*, 2002), and patterns of structural and functional development in the regions comprising these networks (e.g. amygdala, prefrontal and extrastriate visual cortex) are garnering increasing scientific attention. Yet the relationships between pubertal and neural development have rarely been assessed directly in human adolescents (for exceptions see Silk *et al.*, 2009; Blakemore *et al.*, 2010; Forbes *et al.*, 2010, 2011).

Much of what *is* known about physiological changes in the brain during the transition from childhood to adulthood comes from research in animal populations, because adolescent behavior and neural function can be conserved across mammalian species (e.g. with respect to risk-taking; Sisk and Foster, 2004; Spear, 2004). Such homology is convenient to the extent that it allows for an enhanced degree of precision in generating hypotheses about pubertal contributions to

development. Approaches informed by empirical findings at the cellular and molecular levels are particularly relevant to the study of adolescence because they provide an appropriate analytic framework from which to consider the organizational and activational effects of hormones on the brain. For example, sex steroid hormones associated with typical development have been causally linked to changes in the hippocampus for social memory (Hebbard *et al.*, 2003) and reorganization of the visual cortex (Spear, 2009).

Although translational inference cannot speak directly to the role of hormones in human neural development, such findings can inform neuroimaging investigations in the selection and construction of homologous anatomical regions of interest (ROIs), for instance based on the distribution of endocrine receptors in the brains of other species (Goldstein *et al.*, 2001). Two such regions that have received considerable attention in developmental research are the prefrontal cortex (PFC) and the amygdala (Romeo, 2003; Sanz *et al.*, 2008; Schulz *et al.*, 2009). As it has been hypothesized that one of the principle consequences of pubertal increases in hormone levels is to reorganize motivational tendencies, specifically with respect to social targets (Forbes and Dahl, 2010), it seems likely that the PFC and amygala might be critical targets of the endocrine system during the transition to adolescence in humans as well. It is important to note, however, that the extension of conclusions derived from animal models to human adolescents must be undertaken with great care, as there are important differences between humans and other animals at levels of analysis ranging from the molecular (e.g. discrepancies in genetic makeup and expression) to the psychosocial (e.g. media influences on social behavior). Fortunately, advances in neuroimaging technology can help to bridge the gap between research in animal models and investigations of the living human brain.

Human neural development has been studied with both structural and functional magnetic resonance imaging (sMRI, fMRI) for years, but the literature is still relatively limited in scope. Here we briefly summarize known developmental trajectories that are relevant to the core network for processing affective facial displays, which includes both cortical (fusiform gyrus, superior temporal gyrus, post-central gyrus, temporal pole, anterior cingulate gyrus, insula, orbitofrontal cortex, PFC) and subcortical (brainstem, superior colliculus, lateral geniculate and pulvinar nuclei of the thalamus, hypothalamus, corpus striatum, amygdala, hippocampus) regions (Adolphs, 2002). Although total cerebral volume is nearly fully realized by the age of six, the proportions of different tissue types and relative size and composition of various anatomical structures undergo considerable change during the transition from childhood to adulthood (Lenroot and Giedd, 2010). White matter (WM) increases in a linear fashion throughout adolescence, and such increases imply enhanced connectivity between spatially remote areas of the cortex as well as between cortical and subcortical regions. The development of WM is most protracted in the PFC, a region which is crucial not only to response inhibition, planning and executive control (Behrens *et al.*, 2009), but also in computing the value of affective stimuli and determining appropriate behavior in social contexts (Sowell *et al.*, 2002; Rushworth *et al.*, 2007). Gray matter (GM), on the other hand, follows an inverted U-shaped developmental trajectory, with the inflection point occurring earliest in primary sensory cortex and latest in higher-order association cortices like lateral PFC and temporal pole (Giedd and Rapoport, 2010). Situated directly adjacent to the amygdala and orbitofrontal cortex, the temporal pole has been regarded as association cortex for affective perception, integrating sensory information about complex stimuli (e.g. facial expressions) with limbic signals indexing motivational salience and emotional content (Olson *et al.*, 2007). Along with PFC, GM reduction begins latest in the temporal poles, which are not fully mature until well into adulthood (Gogtay *et al.*, 2004).

This U-shaped developmental trajectory is common to a number of anatomical structures, but the exact point in time at which GM volume 'peaks' varies both across neural structures and across individuals (Lenroot and Giedd 2010). For example, the ventral striatum (vS) achieves maximal GM density during late childhood or early adolescence and subsequently undergoes a linear course of volumetric reduction (Sowell *et al.*, 2002). Central components of the limbic system like the amygdala and hippocampus exhibit slight increases in GM density into adulthood, but the rate of change plateaus in early adolescence, suggesting that the vast majority of their macroscopic development is complete shortly after a period of rapid expansion in late childhood (Ostby *et al.*, 2009).

In terms of neural function, there appears to be a similar U-shaped developmental trajectory of amygdalar response to emotional expressions, in which adolescents exhibit stronger amygdala reactivity upon perceiving emotional expressions than either children or adults (Guyer *et al.*, 2008). This has been explained in terms of a temporal mismatch: the subcortical structures are said to reach adult-like levels of functioning during early adolescence, while the relatively immature PFC has yet to achieve the ability to optimally regulate appetitive or aversive emotional signals (Casey *et al.*, 2010; Somerville *et al.*, 2010). For example, early reports posited that immature reward-value computation in the striatum was responsible for increases in adolescent risk-taking (Galvan *et al.*, 2006; Steinberg, 2008).

Recent longitudinal work has also demonstrated that striatal reactivity to emotional displays increases during the transition to adolescence, such that children exhibited increases in vS response from age 10 to 13 (as well as in vmPFC and temporal pole; Pfeifer *et al.*, 2011). Critically, this increase in vS activity was negatively correlated with susceptibility to peer influence and risky behavior, suggesting that the role of the vS in governing behavior is perhaps more complex than simply promoting impulsive approach motivation.

Downloaded from http://scan.oxfordjournals.org/ at James Cook University on March 15, 2015

There was also a longitudinal increase in negative coupling between vS and amygdala while viewing happy and sad facial expressions, relative to neutral ones. However, these findings did not address the influence of puberty on the development of adolescent neural functioning, in vS or elsewhere.

Therefore, an important next step is to simultaneously consider the coordinated activity of neural and endocrine systems in determining behavioral, emotional and psychosocial outcomes for teens (Dahl, 2011). The current investigation sought to address the influence of pubertal development on the neural correlates of affective processing during the transition to adolescence, rather than using age as a proxy for puberty. The ages of 10 and 13 are particularly relevant for addressing such questions, as they allow investigation of late childhood, when relatively few children have experienced significant pubertal development, and early adolescence, when most children have already progressed through the first several stages of puberty (Shirtcliff *et al.*, 2009). Furthermore, these ages represent important developmental epochs from a socioemotional perspective, including the end of elementary school and the end of middle school, respectively. Because data were collected during a tightly constrained window of chronological age during both late childhood and early adolescence, this sample provides a unique opportunity to study pubertal development in a continuous manner within a single timepoint, as well as to consider whether puberty exerts distinct effects in late childhood and early adolescence on the neural correlates of emotion reactivity. Our primary regions of interest, derived from the above literature review, included amygdala, PFC (both medial and lateral aspects), vS and temporal pole.

METHODS

Participants

Typically developing children ($N = 45$, 26 girls) completed data collection at two visits (separated by 36 ± 10 months), and provided high-quality fMRI and behavioral data at both timepoints (M's = 10.1 and 13.1 years, SDs = 0.30 and 0.31 years, at T1 and T2, respectively). Participants and their parents provided written informed assent/consent according to guidelines specified by the Institutional Review Board at UCLA. Participants had no history of significant medical, psychiatric, or neurological disorders.

The Pubertal Development Scale (PDS; Petersen *et al.*, 1988) was completed by participants at both timepoints. On this measure, participants self-report visible development of secondary sexual characteristics. The PDS was always administered with a researcher nearby to answer any questions participants had about the meaning of items. Parents were notified several days in advance of the session that a form assessing pubertal development would be part of the assessment, which gave parents the opportunity to talk with their children about this topic in advance if they so desired. We utilized the scoring guidelines provided by Crockett and colleagues (Petersen *et al.*, 1988), and we omitted the social comparison question (about development relative to the pace of peers). Across all participants, Cronbach's test indicated that the PDS was reliable (five items, $\alpha = 0.80$). There was a highly significant increase from T1 to T2 on the PDS (M's = 1.60 and 2.60, SDs = 0.37 and 0.62 at T1 and T2, respectively; $t(1,44) = 11.36$, $P \sim 0$). At T1, there was no relationship between chronological age and pubertal development [$r(43) = 0.11$, $P = 0.47$]. However, at T2, PDS scores and chronological age were moderately correlated [$r(43) = 0.34$, $P < 0.05$]. See Figure 1 for visualization of raw PDS data at both timepoints. Because there was no significant difference in mean PDS scores for male and female subjects at T1 [$t(1,43) = 0.25$, $P = 0.8$] or T2 [$t(1,43) = 1.55$, $P = 0.13$], fMRI analyses collapsed across gender to increase statistical power.

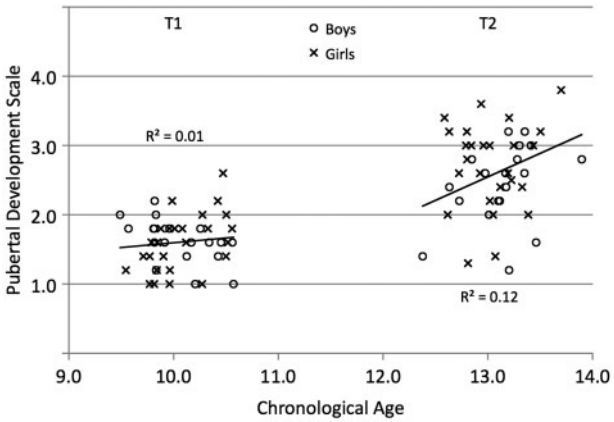

Fig. 1 Correlations between pubertal development and chronological age. Figure 1 depicts the relationship between pubertal development and chronological age at T1 [$r(43) = 0.11$, $P = 0.47$] and at T2 [$r(43) = 0.34$, $P < 0.05$].

Paradigm

During the fMRI scan, participants passively observed full-color, whole-face emotional displays (angry, fearful, happy, sad and neutral) from the NimStim set (Tottenham *et al.*, 2009). Events lasted 2 s, with an interstimulus interval of variable (jittered) length ranging from 0.5 to 1.5 s ($M = 1$ s), and were presented in counterbalanced orders optimized for efficient detection of contrasts between emotions using a genetic algorithm (Wager and Nichols, 2003). A total of 96 whole-brain volumes were acquired on a Siemens Allegra 3.0 Tesla MRI scanner at each time point, including the 80 stimuli described above and an additional 16 null events (fixation crosses at eye-level).

fMRI acquisition and analysis

Data were acquired using a Siemens Allegra 3.0 Tesla MRI scanner. A 2D spin-echo scout (TR = 4000 ms, TE = 40 ms, matrix size 256 by 256, 4-mm thick, 1-mm gap) was acquired in the sagittal plane to allow prescription of the slices to be obtained in the remaining scans.

Downloaded from http://scan.oxfordjournals.org/ at James Cook University on March 15, 2015

The scan lasted 4 min and 54 s (gradient-echo, TR = 3000 ms, TE = 25 ms, flip angle = 90°, matrix size 64 by 64, FOV = 20 cm, 36 slices, 3.125-mm in-plane resolution, 3-mm thick). For each participant, a high-resolution structural T2-weighted echo-planar imaging volume (spin-echo, TR = 5000 ms, TE = 33 ms, matrix size 128 by 128, FOV = 20 cm, 36 slices, 1.56-mm in-plane resolution, 3-mm thick) was also acquired coplanar with the functional scan. Stimuli were presented to participants through high-resolution magnet-compatible goggles (Resonance Technology, Inc.).

Using Automated Image Registration (Woods *et al.*, 1999) implemented in the LONI Pipeline Processing Environment (http://www.pipeline.loni.ucla.edu; Rex *et al.*, 2003), all functional images were (i) realigned to correct for head motion and co-registered to their respective high-resolution structural images using a six-parameter rigid body transformation model, (ii) spatially normalized into a Talairach-compatible MR atlas using polynomial non-linear warping and (iii) smoothed using a 6-mm FWHM isotropic Gaussian kernel. No participant averaged >2.0 mm of motion at either time point (*M*'s = 0.317 and 0.413 mm, SDs = 0.262 and 0.365, at T1 and T2, respectively), and no participant moved >2.0 mm between any image. All coordinates are reported in Talairach space.

Statistical analyses were implemented in SPM8 (Wellcome Department of Cognitive Neurology, London, UK; http://www.fil.ion.ucl.ac.uk/spm/). For each subject, condition effects were estimated according to the general linear model, using a canonical hemodynamic response function, high-pass filtering (128 s), AR(1) and no global scaling. At the fixed effects (single subject) level, linear contrasts were constructed to assess comparisons of interest within individual participants at each timepoint (each of the expressions *vs* null events as well as the average of all expressions *vs* null events). In other words, activity for each emotional expression was contrasted against a resting baseline rather than a low-level control. Because neutral facial expressions are socially meaningful and often elicit considerable activity in regions associated with processing affective salience and uncertainty, results comparing emotional expressions to neutral ones may be difficult to interpret (Kober *et al.*, 2008; Pfeifer *et al.*, 2011). An ideal control is one that possesses the visual complexity of facial expressions with no social or affective content (e.g. scrambled faces; Rahko *et al.*, 2010). Unfortunately, scrambled faces were not included in this paradigm at the outset of the longitudinal investigation. However, comparisons between each facial expression and null events allowed us to identify where neural responses to affective displays were more or less associated with pubertal development (a continuous predictor) across subjects, independent of mean levels of activity. Furthermore, in the group level analyses we could then contrast any of the five facial expressions versus rest, as well as the four emotional expressions versus neutral.

At the group level, we used two complementary analysis strategies. First, in order to specifically examine the effects of puberty on reactivity to all affective displays as well as specific facial expressions at T1 and T2, separate random effects analyses were based on the contrast images from each expression, using each participant's PDS score as the sole predictor. Second, a repeated measures mixed design was employed in order to quantify longitudinal change in neural activity to facial expressions that was associated with pubertal development. In order to assess the influence of puberty independently from that of chronological age, linear regression was conducted to obtain unstandardized residual values of pubertal development, indexing variability in PDS scores that could not be explained by age (in other words, age was used as a covariate in the regression computed to obtain the residualized PDS scores). Including the residualized PDS scores as regressors in this design, with time and emotion as factors, replicated previous reports of longitudinal increases in vS activity for all expressions compared to rest (see Pfeifer *et al.*, 2011, Table 1), despite slight changes in the sample to achieve greater gender balance (increasing proportion of boys and decreasing proportion of girls). Correlations between the BOLD signal elicited by the task and behavioral measures of social, affective and interpersonal functioning used in prior studies conducted on overlapping subsets of participants (Interpersonal Reactivity Index, Davis, 1983; Interpersonal Competence Scale, Cairns *et al.*, 1996; Resistance to Peer Influence, Steinberg and Monahan, 2007; and Indicators of Risk Behavior and Delinquency, Gestsdóttir and Lerner, 2007) did not reveal any significant relationships beyond those reported previously (Pfeifer *et al.*, 2008, 2011). For all whole-brain analyses, results were reported at an alpha threshold of $p < 0.05$ for magnitude at peak voxels, corrected for multiple comparisons using False Discovery Rate (Genovese *et al.*, 2002), and an additional extent threshold of $p < 0.05$ at the cluster level, derived using a Monte Carlo simulation (3dClustSim, the successor to AlphaSim in the AFNI software package; Cox, 1996).

RESULTS

Based on the suite of regression analyses, positive correlations with pubertal development at age 10 were constrained to extrastriate cortex, thalamus and amygdala, while by age 13, level of pubertal development was further correlated with increased activity in the left temporal pole, ventrolateral PFC and ventromedial PFC for the combination of all affective facial displays (see Figure 2; for comprehensive reports of additional activity correlated with pubertal development at each timepoint, see Tables 1 and 2).

Similar patterns were observed when each expression was queried individually, although there were some notable differences. At age 10, pubertal development was correlated with greater activity in extrastriate cortex and thalamus in response to angry, fearful, happy and neutral facial

Table 1 describes neural responses that are significantly correlated with pubertal development at T1. *k* corresponds to the spatial extent of significant clusters (2 mm^3 voxels). *t* represents the *t*-statistic at the peak voxel. *r* indexes the correlation between PDS score and activity at the peak voxel. *x*, *y* and *z* refer to the Talairach coordinates corresponding to the left-right, anterior-posterior and inferior-superior axes, respectively. All activity is reported at a peak threshold of $P < 0.05$ (FDR corrected) and a cluster threshold of $P < 0.05$.

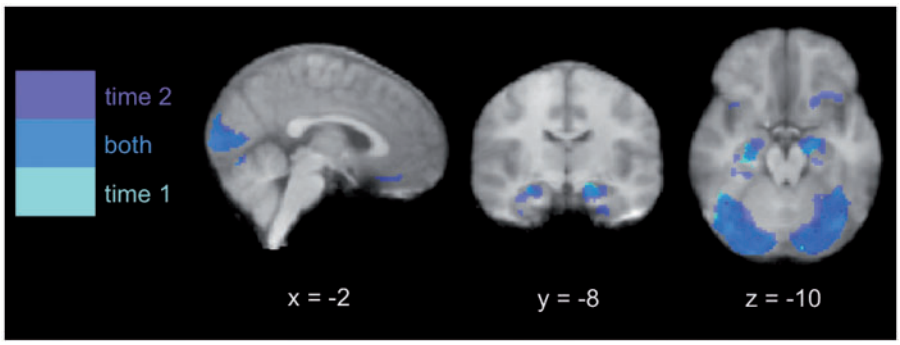

Fig. 2 Correlations between neural activity and pubertal development. Figure 2 depicts activity in extrastriate cortex, amygdala, and hippocampus that correlates with pubertal development at T1 and T2. x, y and z refer to the Talairach coordinates corresponding to the left-right, anterior-posterior and inferior-superior axes, respectively. All activity is displayed at a peak threshold of $P < .05$ (FDR corrected) and a cluster threshold of $P < 0.05$.

expressions. This pattern was even more robust at age 13, and also included the neural response to sad expressions. At 10 years of age, activation in the amygdala was only modulated by pubertal development while viewing neutral facial expressions. However, at age 13, level of pubertal development was associated with significantly greater activation in the amygdala for all five expressions examined, although whether the response was lateralized to the left or right hemispheres, or bilateral, varied by emotion. Furthermore, at age 10 there were no correlations in the temporal pole between pubertal development and neural response to affective facial displays, but by age 13 pubertal development was significantly linked to enhanced activity in temporal pole for happy, sad, fearful and neutral expressions. Positive correlations between pubertal development and ventrolateral PFC response for fearful, neutral and happy expressions were also evident at age 13 but not age 10. Finally, this pattern was replicated in dorsomedial PFC responses, but only for happy facial expressions.

Although there were no statistically significant differences in PDS scores between male and female participants, confirmatory fMRI analyses were carried out to ensure that gender was not a confound. Direct statistical comparisons including gender as a factor revealed no significant differences in the relationship between pubertal development and neural response to facial expressions. However, conducting separate linear regression analyses by gender revealed slight differences in cluster sizes, stereotactic locations and *t*-values. For example, for the average of all expressions compared to rest at T2, activity in ventrolateral PFC was bilateral for girls,

Table 2 describes neural responses that are significantly correlated with pubertal development at T2. *k* corresponds to the spatial extent of significant clusters (2 mm^3 voxels). *t* represents the *t*-statistic at the peak voxel. *r* indexes the correlation between PDS score and activity at the peak voxel. *x*, *y* and *z* refer to the Talairach coordinates corresponding to the left-right, anterior-posterior, and inferior-superior axes, respectively. All activity is reported at a peak threshold of $P < 0.05$ (FDR corrected) and a cluster threshold of $P < 0.05$.

but left lateralized for boys. Such minor differences may have resulted from slight variability between groups in sample size.

Looking to the repeated measures mixed design, no significant relationship between pubertal development (independent of age) and BOLD response to emotional expressions versus neutral ones was apparent at T1. However, at T2 pubertal development (independent of age) was correlated with activity in visual cortex, right amygdala, bilateral hippocampus and temporal pole. These patterns, identified by querying each timepoint individually,

Downloaded from http://scan.oxfordjournals.org/ at James Cook University on March 15, 2015

were statistically different from each other: the positive correlations between pubertal development (independent of age) in visual cortex ([−14, −94, 12], $t = 9.81$), bilateral hippocampus (left: [−24, −32, 4], $t = 4.22$, right: [20, −30, 4], $t = 5.37$), bilateral amygdala (left: [−24, −12, −12], $t = 3.22$, right: [18, −6, −10], $t = 4.47$) and bilateral temporal pole (left: [−42, 16, −12], $t = 3.55$, right: [32, −8, 26], $t = 3.61$) were significantly greater at T2 than T1, as demonstrated by direct comparison of the two timepoints within a repeated measures mixed design. These results imply an interaction between time and pubertal development, insofar as the effects of pubertal development are significantly different between the two waves of data collection. It should be reiterated that this statistical approach used residualized PDS values in order to examine the unique effect of pubertal development, independent from that of age.

DISCUSSION

These results provide evidence of changing relations between pubertal development and neural responses to affective facial displays across the transition from late childhood to early adolescence. Recent longitudinal work focusing on this specific period (Pfeifer *et al.*, 2011) demonstrated age-related increases in a number of key regions of interest, particularly the vS. Here, a different subset of regions exhibited longitudinal increases with respect to pubertal development, including the amygdala and lateral PFC. This is consistent with the idea that puberty per se, and not just age, is associated with enhanced reactivity to socioemotional stimuli, as would be expected in the 'social reorientation of adolescence' (Nelson *et al.*, 2005). Here, neural activity in the amygdala, hippocampus and temporal pole elicited by the affective content of facial displays was significantly correlated with an age-independent measure of pubertal development by age 13, accompanied by significant longitudinal increases in the strength of this coupling.

Our prior longitudinal fMRI study (Pfeifer *et al.*, 2011) observed that, unlike vS reactivity to emotional expressions, the amygdala does not exhibit a significantly greater response at age 13 than at age 10 (except to sad faces). However, we now show that pubertal development enhances amygdala responses to emotions in late childhood, and this link appears to strengthen in early adolescence such that the two are correlated across all expressions individually at this time (happy, neutral, sad, fearful and angry). Activity in the thalamus and extrastriate cortex, structures that work in tandem with the amygdala to process the affective salience of social signals (Adolphs, 2008), shows a similar pattern (although visual cortical regions also exhibit increase over time in the absence of pubertal predictors). These data begin to elucidate the neural foundations of how puberty may 'reorient' adolescents toward social stimuli, such that complex communicative signals like emotional facial expressions begin to take increased relevance as children transition into their teenage years.

Recent findings on social threat and pubertal development have indicated that activity in amygdala and ventrolateral PFC while viewing fearful or neutral faces is stronger during early stages of pubertal development than later stages (Forbes *et al.*, 2011), suggesting that a reduction in threat-related response may be adaptive for adolescents insofar as promoting social approach. The opposite patterns elucidated in the present study may be attributable to differences in fMRI data analysis (e.g. whole brain regression as opposed to ROI analysis), or differences in manner of calculating pubertal development using the PDS. These differences may also be due to the fact that our design employed both longitudinal and cross sectional approaches, or the fact that we also used non-threatening facial expressions such as happiness and sadness.

We discerned another interesting pattern in the responses of several regions that are not significantly related to puberty at age 10, but tightly linked to it at age 13, including the medial PFC, lateral PFC and temporal pole. By early adolescence, the neural response to emotional expressions in these regions is positively correlated with pubertal development. This suggests puberty may affect frontal and temporal association cortices in a way that allows for increasingly mature integration of perceptual and affective information. These higher order cortical areas will continue to develop well into adulthood, and while their functional profile differs for adolescents (Casey *et al.*, 2005; Burnett and Blakemore, 2009; Pfeifer *et al.*, 2009), it is difficult to draw clear boundaries for what constitutes 'mature activity' in any isolated region (Poldrack, 2010). Because adult brain activity is the product of a large number of regions and systems working in concert, the 'maturity' of a functional neural response cannot be fully assessed independently from that of other regions. Thus it may be helpful to frame adolescent neural development in terms of network-wide changes including not only higher-order association cortices, but also their interactions with subcortical regions of interest.

Our findings also demonstrate that different anatomical structures have different developmental profiles. For example, the relationship between puberty and change in amygdala activity appears relatively continuous, as it correlates with pubertal development at both timepoints. The transition from late childhood to early adolescence, however, cannot be explained purely in linear terms. Several important discrete events are also likely to take place within this age range, such as entry into middle school, the start of early romantic relationships, and a shift in self-concept from regarding oneself as a child to internally adopting the mantle of teenager (Pfeifer *et al.*, 2009). However, the relationship between pubertal development and activity in ventrolateral PFC, medial PFC and temporal pole is likely driven by both developmental stage and puberty. The relationship between puberty and responses to emotional stimuli in temporal pole (longitudinal increases which also correlated with increases in resistance to peer influence;

Downloaded from http://scan.oxfordjournals.org/ at James Cook University on March 15, 2015

Pfeifer *et al.*, 2011) in particular speaks to a pattern by which the successful integration of perceptual input from complex social stimuli is gradually incorporated with online emotional processing and inhibitory control. This process is more complex than a simple dichotomy between the roles of subcortical and cortical structures is suited to explain, especially in light of the neural consequences of puberty.

While this work is an important step toward studying adolescence in a more comprehensive manner, it is only a preliminary one. Relationships established in the current work between pubertal development and changes in neural activity of key regions like the amygdala and temporal pole may help lay the foundation for more comprehensive study of the way that the adolescent endocrine system influences the roles of these and other structures in perceiving and experiencing emotion. An ideal advancement would be to simultaneously investigate pubertal changes at multiple levels of analysis (Cacioppo and Berntson, 1992), such as by measuring hormones and administering physical exams in addition to self-report measures and neuroimaging techniques. Also much needed in the field of adolescent neuroscience is the application of methods that allow for data driven, model testing approaches, which will allow investigators to more robustly account for the large number of variables at work. As our understanding of the biological mechanisms underlying adolescent emotion processing grows, we will be better equipped to address the mental health problems, risk-taking behavior and profound social changes that often accompany this developmental epoch. By mapping out the dynamic systems involved in the transition from childhood through adolescence to adulthood, we will be able to better understand how social context, pubertal hormones and neural function simultaneously affect adolescent motivational tendencies and emotional experiences, bringing us closer to unlocking the mysteries of the teenage brain.

Contributed by Richard D. Palmiter, August 2, 1999

Mice that cannot make dopamine (DA), a condition caused by the selective inactivation of tyrosine hydroxylase in dopaminergic neurons, are born normal but gradually become hypoactive and hypophagic, and die at 3 weeks of age. We characterized the feeding and locomotor responses of these DA-deficient (DA−/−) mice to 3,4-dihyroxy-L-phenylalanine (L-DOPA) to investigate the relationship between brain DA levels and these complex behaviors. Daily administration of L-DOPA to DA−/− mice stimulated locomotor activity that lasted 6 to 9 hr; during that time the mice consumed most of their daily food and water. The minimal dose of L-DOPA that was sufficient to elicit normal feeding behavior in the DA−/− mice also restored their striatal DA to 9.1% of that in the wild-type (WT) mice at 3 hr; then DA content declined to <1% of WT levels by 24 hr. This dose of L-DOPA induced locomotor activity that exceeded that of treated WT mice by 5- to 7-fold, suggesting that DA−/− mice are supersensitive to DA. Unexpectedly, DA−/− mice manifested a second wave of activity 24 to 48 hr after L-DOPA treatment that was equivalent in magnitude to that of WT mice and independent of DA receptor activation. The DA−/− mice approached, sniffed, and chewed food during this second period of activity, but they ate <10% of that required for sustenance. Therefore, DA−/− mice can execute behaviors necessary to seek and ingest food, but they do not eat enough to survive.

Rats treated with 6-hydroxydopamine (6-OHDA) and monkeys treated with *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) have been studied extensively as models of Parkinson's disease because both neurotoxins can be used to destroy the same nigrostriatal dopaminergic neurons that die during the progression of the human disease (1, 2). In animal models and in human Parkinson's disease, behavior is generally unaffected until >80% of the dopamine (DA) is depleted. Hypoactivity, deficits in motor coordination, and failure to eat or drink become evident with more severe DA depletion (3–5). The aphagia and adipsia of rats treated with 6-OHDA can be life-threatening unless they are kept alive by intragastric feeding. With this treatment, the rats gradually become more active, and eventually they eat enough food without assistance to stay alive and gain weight. Compensation for the feeding deficit in lesioned animals is thought to occur through improved efficacy of dopaminergic signaling, because DA levels remain low and a subsequent blockade of tyrosine hydroxylase activity will reinstate aphagia and akinesia (6). Although feeding returns to normal, deficits in feeding responses can be elicited by physiological challenges (4, 5). Neonatal rats with 6-OHDA lesions continue to suckle and can be weaned onto normal chow without major impairments of feeding, despite nearly complete elimination of DA. This suggests that compensatory mechanisms are even more efficacious in young rats (2, 7).

Parkinson's disease differs from the rat model in that the symptoms generally become more severe with age, and, as neurons continue to die, tremor is a prominent feature, but aphagia is generally not a major symptom. Food intake may decline as the disease progresses, but it is not clear whether that is attributable to decreased motivation to eat, difficulty in maneuvering eating utensils, or nonspecific depression. The feeding deficit in the rat model has been attributed to sensorimotor impairment and/or a loss of motivation to eat; however, the mechanisms have not been elucidated. Delivery of DA agonists and antagonists to different sites in the brain has identified specific regions that influence feeding behaviors (8, 9), but they have not indicated where the DA action is essential. Furthermore, the genetic approach of inactivating individual genes encoding DA receptors or transporters has not revealed any striking effects on feeding behavior (10–13). Thus, the specific roles of DA in feeding remain enigmatic.

Gene-targeting techniques were used to inactivate the tyrosine hydroxylase gene in dopaminergic neurons, sparing the production of DA as a precursor for norepinephrine and epinephrine (14). Initial studies in these DA−/− mice revealed that DA is important for control of locomotion, muscle coordination, feeding, and probably other behaviors. The variable extent of 6-OHDA lesions, along with a gradual and variable duration of compensation, makes the study of some behaviors difficult in that model. In contrast, the specificity of genetic lesion (resulting in reproducible and stable behavioral phenotypes) provides favorable background for ascertaining where in the brain, and, ultimately how, DA modulates various behaviors. Prolonged restoration of feeding to physiological levels by pharmacological or gene therapy approaches is rarely described in the 6-OHDA-lesion model, although 3,4-dihyroxy-L-phenylalanine (L-DOPA) and DA agonists can reverse some of the symptoms transiently (15–17). Notable exceptions are studies in which transplantation of dopaminergic tissue revealed that local production of DA in striatum could prevent aphagia induced by 6-OHDA (18, 19). Routine pharmacological treatment induces feeding in DA−/− mice, and the feasibility of long-term rescue of feeding behavior (over a year) by gene therapy has been established (20). Our goal is to map more precisely where DA is required to restore various behaviors, including feeding. A prerequisite to such studies, however, is characterization of behavioral deficits of DA−/− mice.

Materials and Methods

Mice. DA−/− mice were created as described (14). The wild-type (WT) and DA−/− mice in this study were 3- to 6-month-old male and female hybrids of 129/SvEv × C57BL/6J. Because no significant differences between heterozygous and WT mice were observed in any of the parameters measured, they were grouped and designated as WT mice. Mice were housed under standard vivarium conditions and maintained on a 12-hr light/dark cycle with the lights on at 07:00. For routine maintenance of mutants, daily injections of 50 mg/kg L-DOPA were administered to DA−/− mice between 12:00 and 16:00. The genotypes of all mice were assessed by Southern blot analysis.

Activity Measurements. Transparent Plexiglas cages (40 × 20 × 20 cm) were placed on a rack equipped with infrared photobeams (San Diego Instruments) to measure the ambulatory activity of

Abbreviations: DA, dopamine; DA−/−, dopamine-deficient; L-DOPA, 3,4-dihyroxy-L-phenylalanine; 6-OHDA, 6-hydroxydopamine; WT, wild type.

the mice. The number of consecutive beam-breaks that occurred each hour was measured and converted to meters by using the distance between beams (8.8 cm) as a conversion factor.

Neurological and Sensorimotor Examinations. WT (n = 10) and DA−/− (n = 10) mice were subjected to 13 neurological tests and 1 activation test (forced swim) that had previously been used to assess the capacities of 6-OHDA-lesioned rats (21). Catalepsy and biting strength tests were modified to make them suitable for mice. Catalepsy and akinesia tests were performed in the home cage. Mice did not respond to the tactile or noxious stimuli tests designed for rats; these tests were therefore omitted. Tests were performed at 1 and 24 hr after an L-DOPA injection, and mice were scored on a scale of 0 (poor) to 4 (normal).

Food Intake Measurements and Videotaping of Feeding Behavior. Fresh food pellets were placed in the bottom of the cage each day and water was available from 15- or 50-ml bottles equipped with spouts. The amount of food consumed was quantified by weighing the food pellets before and after each test interval and the difference was recorded. Water intake was quantified by weighing bottles in the same fashion. To keep DA−/− mice alive without L-DOPA treatment, Ensure Plus (Abbott Labs) was dispensed in small drops with a syringe and a blunt 30-gauge needle in front of the mouth of hand-held DA−/− mice (n = 3), beginning at postnatal day 21. Mice were routinely maintained on breeder chow (Purina 5015), which contains 11% fat and yields 4.35 kcal/g. For some experiments, we used a standard low-fat chow (Harlan 8604) with 3.93 kcal/g, or a high-fat, high-sucrose, soft palatable chow (Research Diets, D12331) with 5.56 kcal/g. For videotaping of feeding behavior, WT (n = 3) and DA−/− (n = 3) mice were fed the high-fat, high-sucrose, soft, palatable chow for 2 weeks. Food was removed on day 15, and 30 hr later, cage tops were carefully removed and a cup filled with the same type of chow was placed on the bottom of the cage. Reaction of the mice was videotaped for 90 min and the amount of food consumed was determined as described above.

Drug Administration. Drugs were prepared in 10 mM sodium phosphate, 150 mM NaCl, pH = 7.5 (PBS) or 0.9% NaCl. Solutions of L-DOPA (Sigma) at 1.5 mg/ml and the methyl ester of L-DOPA (Research Biochemicals International) at 3 mg/ml were prepared in PBS containing 2.5 mg/ml ascorbic acid (Sigma). Carbidopa (Sigma) was added to L-DOPA solutions at concentrations that allowed for delivery of either 12.5 or 25 mg/kg carbidopa with the standard 50-mg/kg dose of L-DOPA. Amphetamine (Sigma), SCH 23390 (Research Biochemicals International), and haloperidol (McNeil Pharmaceutical) were prepared in 0.9% saline. All drug solutions were delivered via intraperitoneal injection in a volume that did not exceed 1 ml.

D1- and D2-Receptor Antagonist Studies. Mice were placed in activity chambers for at least 12 hr before treatment with 0.9% saline or DA receptor antagonists (SCH 23390 and haloperidol); beam breaks were recorded over 4 hr. The DA−/− mice were treated with 50 mg/kg L-DOPA either 2 or 26 hr before antagonist treatment, such that activity measurements were performed 2 to 6 and 26 to 30 hr after L-DOPA administration.

Monoamine Measurements. The brains of the CO_2-asphyxiated, WT and DA−/− mice were removed and immediately placed in ice-cold PBS for 2 min. Dissections were performed on a glass plate chilled to 4°C, and structures of interest were frozen on dry ice in microcentrifuge tubes and stored at −70°C until analysis. Monoamine measurements were performed as described (22).

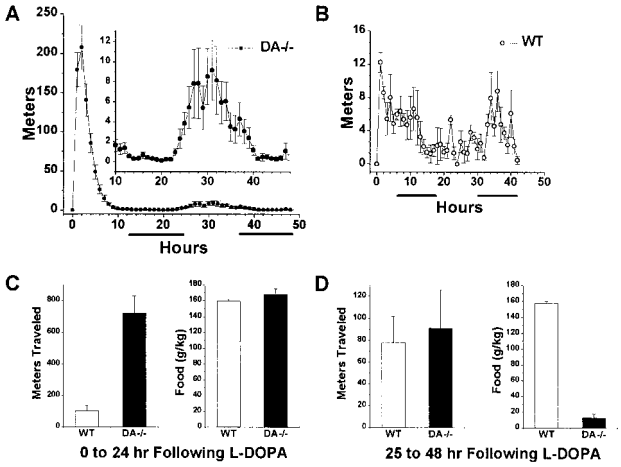

Fig. 1. DA−/− mice exhibit hyperactivity immediately after L-DOPA treatment, and display a second wave of activity that occurs 30 hr after treatment. Ambulatory activity of DA−/− mice (*A*; n = 17] and WT mice (*B*; n = 8). (*C* and *D*) Black bars represent the dark cycle. Total distance traveled and amount of food consumed by DA−/− and WT mice in the first 24-hr period (*C*) and second 24-hr period (*D*) after L-DOPA treatment.

Results

Locomotor Activity of DA−/− Mice After Injection of L-DOPA. Daily administration of 50 mg/kg L-DOPA into DA−/− mice induced locomotor activity that greatly exceeded that of L-DOPA-treated WT mice for 6 to 9 hr; by 24 hr, however, the DA−/− mice had become hypoactive (Fig. 1*A*). Because the DA−/− mice remained hyperactive for an entire day when injected every 4 hr with 100 mg/kg L-DOPA, and they traveled up to 3000 meters/day (data not shown), the decline in activity after the first few hours was not caused by fatigue. The overall distance traveled by DA−/− mice during the first 24 hr after treatment was 7-fold greater than that of WT mice (Fig. 1*C*). An unexpected second wave of activity occurred between 24 and 40 hr after the previous L-DOPA treatment (Fig. 1*A*, *Inset*). The mean distances traveled by DA−/− and WT mice between 24 and 48 hr after an L-DOPA injection were equivalent (Fig. 1*D*); however, during this period of activity DA−/− mice typically displayed a hunched appearance, walked with an awkward gait, and performed poorly on rotarod and pole tests (23).

The distance traveled by DA−/− mice increased marginally as the dose of L-DOPA was increased to 20 mg/kg, then steadily increased to reach a plateau between 40 and 100 mg/kg L-DOPA (Fig. 2*A*). None of these dosages of L-DOPA had any effect on WT mice.

Neurological and Sensorimotor Examination of WT and DA−/− Mice. Mice performed well on many of the neurological tests (Table 1). DA−/− mice scored 486 (1 hr after L-DOPA), but only 379 (24 hr after L-DOPA) out of a possible 520 points, compared to 495 for WT mice. DA−/− mice tested 24 hr after L-DOPA treatment displayed greater one- and four-limb akinesia and forelimb catalepsy than did WT mice (Table 1). When tested 1 hr after L-DOPA treatment, the DA−/− mice were deficient in the paw-pinch assay. The performance of the DA−/− mice in the forced-swim test 24 hr after L-DOPA treatment was equivalent to that of the WT mice.

Food Consumption of DA−/− Mice in Response to L-DOPA. DA−/− mice can be maintained for at least 1.5 yr with daily administration of 50 mg/kg L-DOPA if they are fed breeder chow (4.35 kcal/g); standard chow (3.93 kcal/g), however, is inadequate for survival. With treated daily with L-DOPA injections at 25 mg/kg,

Downloaded by guest on February 23, 2022

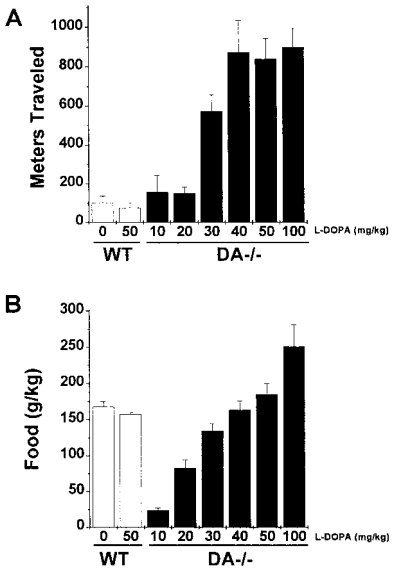

Fig. 2. Low doses of L-DOPA cause hyperactivity in DA−/− mice. Individually housed DA−/− mice during the 9-hr period after administration of 10, 20, 30, 40, or 50 mg/kg or 100 mg/kg L-DOPA methyl ester were used to generate a dose-response curve. Various doses of L-DOPA were administered 24 hr after their last L-DOPA injection. (*A*) Ambulatory activity of WT ($n = 8$) and DA−/− mice ($n = 8$). (*B*) Food consumed by WT ($n = 8$) and DA−/− mice ($n = 8$).

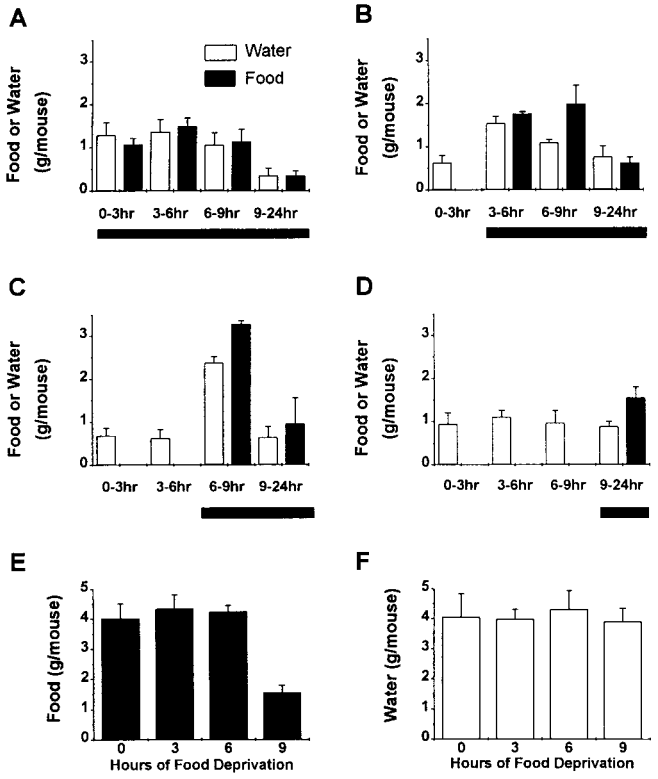

Fig. 3. Food deprivation identifies the minimal amount of DA required to sustain food consumption in DA−/− mice. Mice ($n = 15$) housed in groups of three were treated with 50 mg/kg L-DOPA, returned to their home cages, and food was added after 3, 6, or 9 hr of restriction. Water was available ad libitum during the food restriction studies. Amount of food and water consumed after 0 (*A*), 3 (*B*), 6 (*C*), or 9 (*D*) hr of food deprivation is shown. Black horizontal lines represent the time when food was present in the cage. (*E*) Total amount of food consumed when mice were food-deprived after L-DOPA treatment. (*F*) Water consumed by food-deprived DA−/− mice.

the DA−/− mice lost weight and would have succumbed if this regimen had continued.

DA−/− mice housed together consumed about 30% of their total daily food and water during each of the first three 3-hr periods, and the remaining 10% was consumed during the next 15 hr (Fig. 3*A*). Water and food consumption by the two groups were comparable during the 24 hr. The total amounts of food consumed by DA−/− and WT mice during the first 24 hr after L-DOPA treatment were similar; however, during the next 24 hr, the DA−/− mice ate only 10% as much food as did the WT mice (Fig. 1 *C* and *D*). Food intake was proportional to the L-DOPA dose up to 100 mg/kg (Fig. 2*B*).

In another experiment, DA−/− mice were injected with L-DOPA but food was unavailable until 3, 6, or 9 hr later; water was available all the time. When food was restored 3 or 6 hr after the L-DOPA injection, the DA−/− mice compensated by eating more during the next 3-hr period (Fig. 3 *B* and *C*); by 24 hr, they had consumed the same amount of food as under ad libitum conditions (Fig. 3*E*). However, if food was restored at 9 hr, the DA−/− mice ate only 35% of the daily requirement (Fig. 3 *D* and *E*), but they consumed normal amounts of water even when food consumption fell below normal (Fig. 3 *E* and *F*). Although food and water consumption normally occurred in parallel (Fig. 3*A*), they can be dissociated (Fig. 3 *B–D*).

Table 1. Neurological testing of WT and DA−/− mice

	Test score		
	WT	DA−/− mice	
Test	24 hr	1 hr	24 hr
Screen paw placement	40	40	40
One-limb akinesia	39	40	14***
Four-limb akinesia	40	40	9***
Turning on a tilted screen	35	29	7**
Forelimb catalepsy	40	39	14***
Visual placing	36	39	32
Orientation to paw pinch	40	33*	37
Auditory response	40	40	40
Vestibular response	40	40	40
Splay posture	40	40	40
Biting strength	25	26	26
Righting reflex	40	40	40
Hind-limb extensor rigidity	40	40	40
Total	495	486	379

Neurological tests were performed on WT and DA−/− mice 1 and 24 hr after L-DOPA treatment. No differences were observed in WT mice at 1 and 24 hr. Maximum possible score for each test was 40 (4 × 10 mice). Significance was assessed by standard ANOVA. *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$ compared with WT mice.

The Feeding Behavior of DA−/− Mice. Hand-held, young DA−/− pups that had never been injected with L-DOPA would lick and swallow small drops of a liquid diet placed by their mouth. With frequent feeding by this method, the mice ate enough to maintain body weight for a week without L-DOPA treatment; however, if left with their mother, they would have died.

When presented with a palatable, high-sucrose, high-fat diet after a 30-hr fast, the adult DA−/− and WT mice approached, sniffed, and began to consume the food; but consumption by the DA−/− mice was short-lived compared with that of the WT mice. After 90 min, most of the DA−/− mice were inactive or sleeping, whereas WT mice were still moving about the cage and occasionally eating. The amount of food eaten by the DA−/−

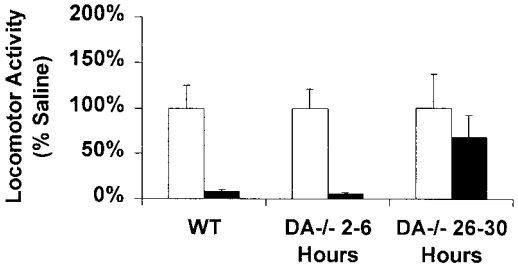

Fig. 4. DA receptor antagonists do not block the second wave of locomotion displayed by DA−/− mice. Ambulatory activity of WT and DA−/− mice treated with 0.9% saline (open bars) or a mixture of 0.1 mg/kg SCH 23390 and 2 mg/kg haloperidol (closed bars) shown as percent of saline-elicited activity. Meters traveled ± SEM: WT saline = 24.6 ± 6.2; DA−/− saline (2–6 hr) = 281.1 ± 59.3; and DA−/− saline (26–30 hr) = 17.9 ± 6.7.

mice was only 25% that of the WT mice during this 90-min period.

The Second Wave of Activity. The second wave of activity may have been caused by the release of residual DA. To test this possibility, a mixture of D1- and D2-receptor antagonists (SCH 23390 and haloperidol, respectively) was administered during the second wave of activity and locomotion was monitored. The DA-receptor antagonists reduced locomotion by more than 90% in WT and DA−/− mice during the first wave of activity (Fig. 4). The same mixture of antagonists had no significant effect on the locomotion of DA−/− mice during the second wave of activity (Fig. 4).

Amphetamine stimulates locomotion in rodents by inducing the release of DA from dopaminergic terminals (24, 25). Administration of 5 mg/kg amphetamine to DA−/− mice 19 hr after their last treatment with L-DOPA stimulated ambulatory activity. However, the response of DA−/− mice was completed within 1 hr, compared with 2 hr for WT mice (Fig. 5*A*). The WT mice responded similarly to a second dose of amphetamine given 2 hr after the first dose, whereas the DA−/− mice were completely unresponsive to a second dose (Fig. 5*A*). The locomotor response of DA−/− mice to amphetamine was completely blocked by a combination of D1- and D2-receptor antagonists (data not shown). Fig. 5*B* demonstrates that a second wave of activity occurred on schedule even when residual DA was depleted by amphetamine.

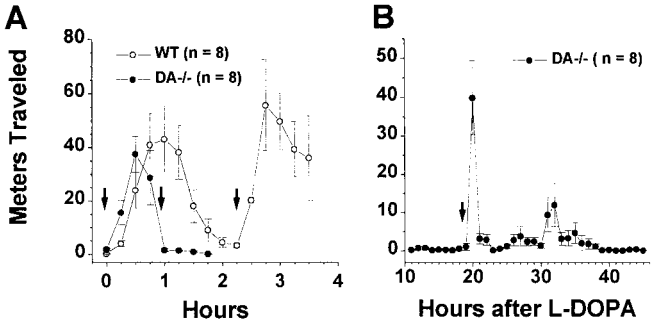

Fig. 5. Amphetamine induces locomotor behavior in DA−/− mice, but amphetamine treatment does not block the second wave of activity displayed by DA −/− mice. (*A*) Ambulatory activity of WT and DA−/− mice given two consecutive injections of 5 mg/kg amphetamine. Arrows indicate times of amphetamine administration. (*B*) Amphetamine (5 mg/kg) was administered 19 hr after the L-DOPA injection and activity was monitored for an additional 36 hr. Arrow indicates time of amphetamine injection.

Table 2. Catecholamine content in WT and DA−/− mice

Group	Brain region	*n*	Time after treatment, hr	L-DOPA, mg/kg	DA, ng/mg protein
WT	Striatum	7	0	Naïve	108.05 ± 12.02

WT and DA−/− mice were injected with L-DOPA, L-DOPA methy ester (†), or L-DOPA + 25 mg/kg carbidopa (CD), and animals were sacrificed at 3, 6, 9, or 30 hr after treatment. Naïve mice did not receive injection of L-DOPA and were sacrificed when 17 to 20 days old. Brains from all mice were removed and dissected and catecholamine concentrations were measured with HPLC and electrochemical detection. Significance was assessed by standard two-tailed *t*-test analysis. *, $P < 0.05$ compared with WT mice; **, $P < 0.05$ compared with naïve DA−/− mice.

Brain DA Content Is Only Partially Restored by L-DOPA. At the peak of activity, 3 hr after the standard dose of 50 mg/kg L-DOPA, the highest DA content was found in the striatum, but it was only 9.1% of the WT levels (Table 2). At 9 hr, when there was insufficient DA to support normal food consumption (Fig. 3*E*), DA content was 3.8% of normal; at 30 hr, DA levels were <1% of normal (Table 2). The ratio of DA to norepinephrine in the striatum of naïve DA−/− mice never injected with L-DOPA was 0.08, not significantly different from the ratio obtained at 30 hr (0.1). This value is also similar to the ratio observed in brain regions that contain few dopaminergic projections (e.g., cerebellum) and several peripheral tissues (22). Administration of 100 mg/kg of the L-DOPA methyl ester raised brain DA content in the striatum (28.2% of normal) but not in the midbrain (Table 2). Norepinephrine and serotonin levels were normal in DA−/− mice 3 and 30 hr after L-DOPA treatment (data not shown).

Carbidopa Elevates Brain DA Concentrations and Induces Stereotypy. To achieve higher levels of L-DOPA in the brain, peripheral L-aromatic amino acid decarboxylase activity was inhibited by coinjecting carbidopa. Administration of L-DOPA and carbidopa restored DA content within the striatum to normal levels and to more than normal levels in the midbrain (Table 2). In addition, the concentration of the primary DA metabolite, dihydroxyphenylacetic acid (DOPAC), was elevated in all brain

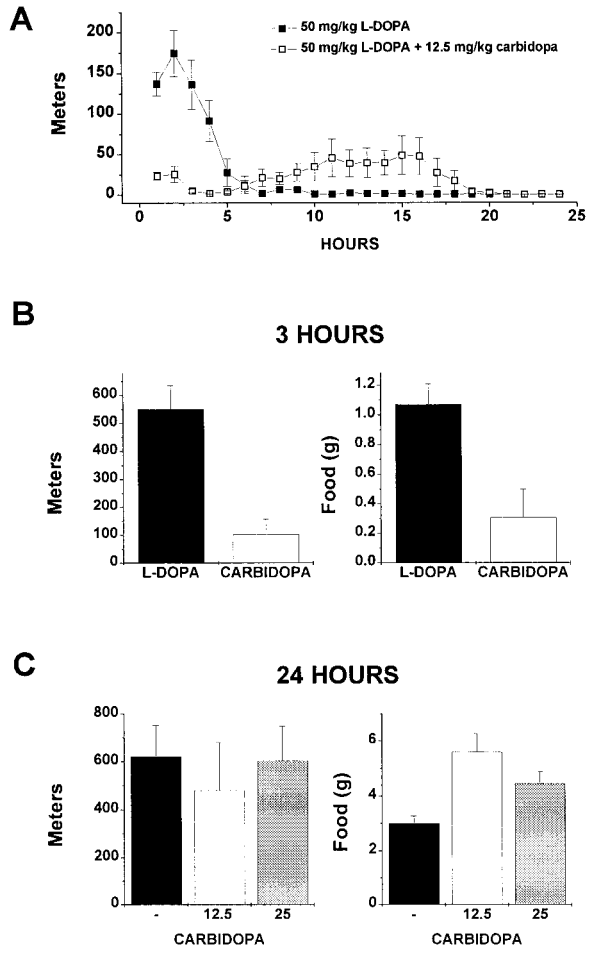

Fig. 6. Simultaneous carbidopa and L-DOPA treatment induces stereotypy in DA−/− mice. (*A*) Ambulatory activity of DA −/− mice ($n = 8$) treated with 50 mg/kg L-DOPA (■) or a mixture of 50 mg/kg L-DOPA and 12.5 mg/kg carbidopa (□) parse by 1-hr intervals. (*B*) Total meters traveled and food consumed by DA−/− mice in the first 3 hr after injection of 50 mg/kg L-DOPA alone (black bars) or 50 mg/kg L-DOPA and 12.5 mg/kg carbidopa (open bars). (*C*) Total meters traveled and food consumed by DA−/− mice in 24 hr when treated with 50 mg/kg L-DOPA alone (black bars), a mixture of 50 mg/kg L-DOPA and 12.5 mg/kg (open bars), or 50 mg/kg L-DOPA and 25 mg/kg carbidopa (gray bars).

regions, suggesting that DA turnover was elevated (data not shown). When carbidopa at 12.5 or 25 mg/kg was given with the standard 50 mg/kg dose of L-DOPA, it produced a biphasic activity profile, with a lull in ambulatory activity between 1 and 5 hr (Fig. 6*A*). During this lull, DA−/− mice typically sat upright with their paws together and engaged in intense stereotypic behavior that included licking and chewing of paws and occasionally self-mutilation. This treatment produced less locomotor activity and feeding during the 3 hr after treatment than that achieved by L-DOPA alone (Fig. 6*B*), but activity resumed and persisted much longer, such that during the 24 hr, these mice traveled a distance similar to that when they were given L-DOPA alone. The mice also ate more food with either dose of carbidopa (Fig. 6*C*). WT mice treated with L-DOPA and either dose of carbidopa became inactive and did not exhibit stereotypy.

Discussion

There is extensive literature implicating DA in movement, sensorimotor function, and feeding. DA−/− mice are unable to synthesize DA in dopaminergic terminals without pharmacological intervention or gene therapy, and consequently, when depleted of DA, they display defects in many of these activities. When DA−/− mice are treated with L-DOPA, the concentration of DA restored in the brain is only a fraction of WT levels (Table 2), but they manifest locomotor activity that reaches 200 meters/hr, about 20 times that of WT mice (Fig. 1*A*). Food consumption is normal with this routine L-DOPA treatment (Fig. 1*C*). These results demonstrate that DA−/− mice are supersensitive to brain DA. This supersensitivity to DA does not appear to be caused by differences in the number of DA receptors or in the DA transporter, as measured by ligand binding, suggesting that it resides in more efficient coupling of DA receptors to the signal transduction (unpublished observations).

Adult 6-OHDA-lesioned rats fail to move, eat, or drink for several days after surgery, but with assistance, the rats will progress through several stages of behavioral recovery and eventually regain the ability to perform these behaviors (26). In the early stages of recovery, a phenomenon called "paradoxical kinesia" can be elicited in which activity and feeding can be restored for a short time by presentation of novel stimuli (21, 27). DA−/− mice resemble rats in this early stage; they become hypoactive, aphagic, and adipsic, and "paradoxical kinesia" can be induced 24 hr after L-DOPA treatment. Even without stimulation, DA−/− mice undergo a DA-independent wave of motor activity 24–48 hr after L-DOPA treatment (Figs. 1 and 4). During this second wave of activity, the DA−/− mice approach, sniff, chew, and swallow food, but they consume only a fraction of that needed for sustenance. In the rat 6-OHDA model, there is gradual compensation for the feeding deficit when the lesions are performed in adults, and no deficits are observed after neonatal lesions; in both cases, brain DA levels are reported as $<$ 2% of normal. Although increases in serotonin have been observed (28, 29), normal feeding continues to depend on DA; i.e., a second 6-OHDA treatment or inhibition of tyrosine hydroxylase activity reinstates aphagia (6). We observe insufficient feeding in DA−/− mice when DA falls below 3.8% of normal (9 hr after L-DOPA administration), serotonin levels are unaltered, and compensation is not observed even after a year of daily L-DOPA treatments.

Responses of DA−/− mice in 9 of 13 tests that involve external stimuli, as well as the forced-swim test, were normal and unaffected by L-DOPA treatment. However, their responses in 4 tests that involve voluntary or coordinated movement were impaired 24 hr after L-DOPA but were restored 1 hr after L-DOPA treatment (Table 1). This finding is in agreement with the inability of DA−/− mice to perform other motor tasks that require coordinated movement (pole and rotarod test) when DA is depleted (14, 20). Overall, DA −/− mice performed at 76.6% (1 hr after L-DOPA) and 98.2% (24 hr after L-DOPA) of WT mice on these tests. DA−/− mice ambulate normal distances during the second 24 hr period after L-DOPA treatment without consuming the normal amount of food. However, they ate normally for a short time when presented with palatable food during that period. They could also be kept alive for over a week without L-DOPA treatment by hand-feeding them a liquid diet. These observations indicate that DA−/− mice can execute behaviors required for seeking and ingesting food; however, without L-DOPA treatment they will die of starvation even with easy access to palatable food. Likewise, DA−/− pups with a nursing mother will not suckle enough to sustain themselves.

It is noteworthy that adult rats with severe 6-OHDA lesions were maintained by gastric feeding rather than pharmacologically. In that model, dopaminergic terminals are almost completely destroyed and those that remain probably manifest maximal activity; hence DA release cannot be enhanced by administering L-DOPA. We have found it difficult to restore normal feeding (or other behaviors) of DA−/− mice with

Downloaded by guest on February 23, 2022

direct-acting DA agonists and the same may be true for lesioned rats. Thus, activity-dependent release of DA from dopaminergic terminals (perhaps along with other neuromodulators) may be necessary for normal feeding.

An optimal level of dopaminergic signaling may be required for the mice to engage in normal behaviors. Peripherally administered DA agonists or antagonists inhibit feeding in both WT and partially lesioned rats, suggesting that acute elevation or dampening of DA signaling adversely affects rat feeding behavior (8, 30). DA−/− mice also have an optimal range of brain DA levels (3.5–25% of normal) that can support normal feeding. When DA falls below that range, the mice do not consume adequate amounts of food; when DA rises above that range, intense stereotypic behaviors interfere with feeding. Elevation of brain DA concentrations to WT levels causes DA−/− mice to engage in intense stereotypy and forego eating for several hours; but when DA levels begin to decline, they ambulate and feed as when injected with L-DOPA alone (Fig. 6 *A–C*). The maximal locomotor response observed with this treatment does not reach the magnitude obtained with L-DOPA treatment alone, but activity and feeding are prolonged.

What neuromodulator(s) induce the second wave of locomotor activity? We suspect that the second wave of activity is the consequence of a circadian input. Considering that dopaminergic neurons are intact in this model, the simplest suggestion is that these neurons normally liberate neuromodulators (in addition to DA) that contribute to voluntary locomotion. In the absence of DA, these other neuromodulators may continue to stimulate locomotion in response to circadian inputs. Neuromodulators/neurotransmitters, such as cholecystokinin, neurotensin, ATP, adenosine, or glutamate are candidates (31–35). Alternatively, the circadian activity may be completely independent of inputs from dopaminergic neurons.

The DA−/− mice reveal that DA is essential for normal feeding. The same conclusion was reached many years ago by several investigators studying rats with 6-OHDA lesions; however, the insult produced by destroying neurons greatly exceeds that resulting from the removal of a single enzyme. Thus, it is remarkable that the 6-OHDA lesions and genetic model are so similar, despite the fact that dopaminergic neurons produce many neuromodulators in addition to DA.

NEUROSCIENCE

Coupled electrophysiological, hemodynamic, and cerebrospinal fluid oscillations in human sleep

Nina E. Fultz[1,2], Giorgio Bonmassar[2,3], Kawin Setsompop[2,3], Robert A. Stickgold[4,5], Bruce R. Rosen[2,3], Jonathan R. Polimeni[2,3], Laura D. Lewis[1,2]*

Sleep is essential for both cognition and maintenance of healthy brain function. Slow waves in neural activity contribute to memory consolidation, whereas cerebrospinal fluid (CSF) clears metabolic waste products from the brain. Whether these two processes are related is not known. We used accelerated neuroimaging to measure physiological and neural dynamics in the human brain. We discovered a coherent pattern of oscillating electrophysiological, hemodynamic, and CSF dynamics that appears during non–rapid eye movement sleep. Neural slow waves are followed by hemodynamic oscillations, which in turn are coupled to CSF flow. These results demonstrate that the sleeping brain exhibits waves of CSF flow on a macroscopic scale, and these CSF dynamics are interlinked with neural and hemodynamic rhythms.

Sleep is crucial for both high-level cognitive processing and also basic maintenance and restoration of physiological function. During human non–rapid eye movement (NREM) sleep, the electroencephalogram (EEG) exhibits low-frequency (<4 Hz) oscillatory dynamics that support memory and neural computation (*1*–*8*). In addition, functional magnetic resonance imaging (fMRI) studies measuring blood oxygen level–dependent (BOLD) signals have demonstrated widespread hemodynamic alterations during NREM sleep (*9*–*15*). Sleep is also associated with increased interstitial fluid volume and clearance of metabolic waste products into the CSF (*16*), and clearance is stronger in sleep with more low-frequency EEG oscillations (*17*). Why these diverse physiological processes co-occur in this state of low arousal is not known. In particular, it remains unclear how CSF dynamics change during sleep and how they relate to the major changes in neural activity and hemodynamics.

We simultaneously measured BOLD fMRI dynamics, EEG, and CSF flow during human sleep. To achieve high–temporal-resolution imaging, we acquired fMRI data at fast rates [repetition time (TR) < 400 ms]. While fMRI is often used to detect local oxygenation changes, fast acquisition paradigms also enable detection of fluid inflow: Fresh fluid arriving at the edge of the imaging volume has high signal intensity because it has not yet experienced radiofrequency pulses (fig. S1). By placing the boundary edge of the imaging volume at the fourth ventricle (Fig. 1A), CSF flow into the brain was detected as increased signal in the lower slices (Fig. 1B), allowing us to measure dynamics of CSF flow simultaneously with BOLD fMRI. We combined this imaging with simultaneous EEG (n = 13 participants) and identified continuous segments of clear stable wake or NREM sleep with low motion (fig. S2 and materials and methods) to enable analysis of continuous low-frequency dynamics.

We first investigated whether sleep was associated with distinct CSF flow dynamics (Fig. 1, C to E). During wakefulness, the CSF signal exhibited a small-amplitude rhythm synchronized to the respiratory signal at ~0.25 Hz (Fig. 1, E and G), consistent with previous studies (*18*, *19*). By contrast, during NREM sleep, we observed a large oscillation in the CSF signal at 0.05 Hz (Fig. 1, E and G). We analyzed this CSF signal across all sleep segments, confirming that identified sleep segments exhibited low-frequency EEG signatures of NREM sleep (Fig. 1F). We found a 5.52-dB increase in the CSF signal peaking at 0.05 Hz during sleep (Fig. 1, G and H, and fig. S2) [95% confidence interval (CI) = (2.33, 7.67); P = 0.003, signed-rank test], suggesting that large waves of CSF inflow occur approximately every 20 s. We additionally analyzed nearby non-CSF regions of interest (ROIs) with matched slice positioning and saw no such effect [change = −0.03 dB, CI = (−2.7, 1.3); P = 0.003 for difference, signed-rank test], suggesting that this sleep-associated pattern was specifically driven by physiological signals in the ventricle (Fig. 1I).

Because inflow signals are caused by fluid flowing into the acquisition volume, CSF flow signals should be brightest in edge slices and decay as fluid passes into central slices (Fig. 2, A and B, and fig. S1). We indeed observed a gradient of signal amplitudes across the slices (Fig. 2, C and D). Some large inflow events exhibited equally bright amplitudes across the lower slices (Fig. 2D), suggesting the CSF flow velocity had exceeded the imaging critical velocity (11.4 mm/s for slice 2). Together, these results identified a large-amplitude pulsatile flow of CSF at 0.05 Hz that appears during NREM sleep.

We next examined whether these slow macroscopic CSF oscillations were linked to hemodynamic signals. Previous studies have proposed microscopic arterial pulsation, corresponding to the ~1-Hz cardiac cycle, as a mechanism for driving interstitial fluid flow (*20*–*23*). To test what might generate the much slower macroscopic CSF rhythm we observed, we analyzed the changes in BOLD signal during sleep. We observed an increase in BOLD signal amplitude in the cortical gray-matter fMRI signal during sleep, as compared with wakefulness (Fig. 3A versus B and C) [mean = 3.28 dB; CI = (0.09, 6.54); P = 0.032, signed-rank test], consistent with previous reports of low-frequency BOLD fluctuations during sleep (*9*, *10*, *24*). Furthermore, the CSF signal was tightly temporally coupled to the cortical gray-matter BOLD oscillation during sleep (Fig. 3, A and B), exhibiting a strong anticorrelation (fig. S3) (maximal r = −0.48 at lag 2 s, P < 0.001, shuffling).

This anticorrelation suggested a possible alternation of blood flow and CSF flow during sleep. We hypothesized that the BOLD oscillations corresponded to an oscillation in cerebral blood volume and that, because of constant intracranial volume, more CSF flows into the head when less volume is occupied by the blood (*25*, *26*). This hypothesis predicts that the CSF signal should approximately match the negative derivative of the BOLD oscillation, after setting negative values to zero (materials and methods). Consistent with this hypothesis, the CSF time series and the thresholded derivative BOLD signals were strongly correlated (Fig. 3, D and E) (maximal r = 0.59 at lag −1.8 s; P < 0.001, shuffling).

We next examined whether neural activity was linked to these coupled hemodynamic and CSF oscillations during sleep. In conventional fMRI, the BOLD response is elicited by neural activity, which drives flow of oxygen-rich blood (*27*, *28*), and EEG oscillations are associated with hemodynamic signals (*29*–*32*). We therefore hypothesized that the large, slow-delta (0.2 to 4 Hz) electrophysiologic oscillations characteristic of NREM sleep could be coupled to oscillations in blood volume and, in turn, displacement effects on CSF flow. We analyzed the instantaneous amplitude of slow-delta EEG relative to the peak of the CSF waves and found that neural, BOLD, and CSF waves were coupled (Fig. 4, A to C, and fig. S4). The neural waves preceded the CSF waves, with a peak in slow-delta EEG occurring 6.4 s before the CSF peak (peak amplitude = 21%, P < 0.001, shuffling). We calculated the best-fit impulse response between the EEG and CSF (Fig. 4D)

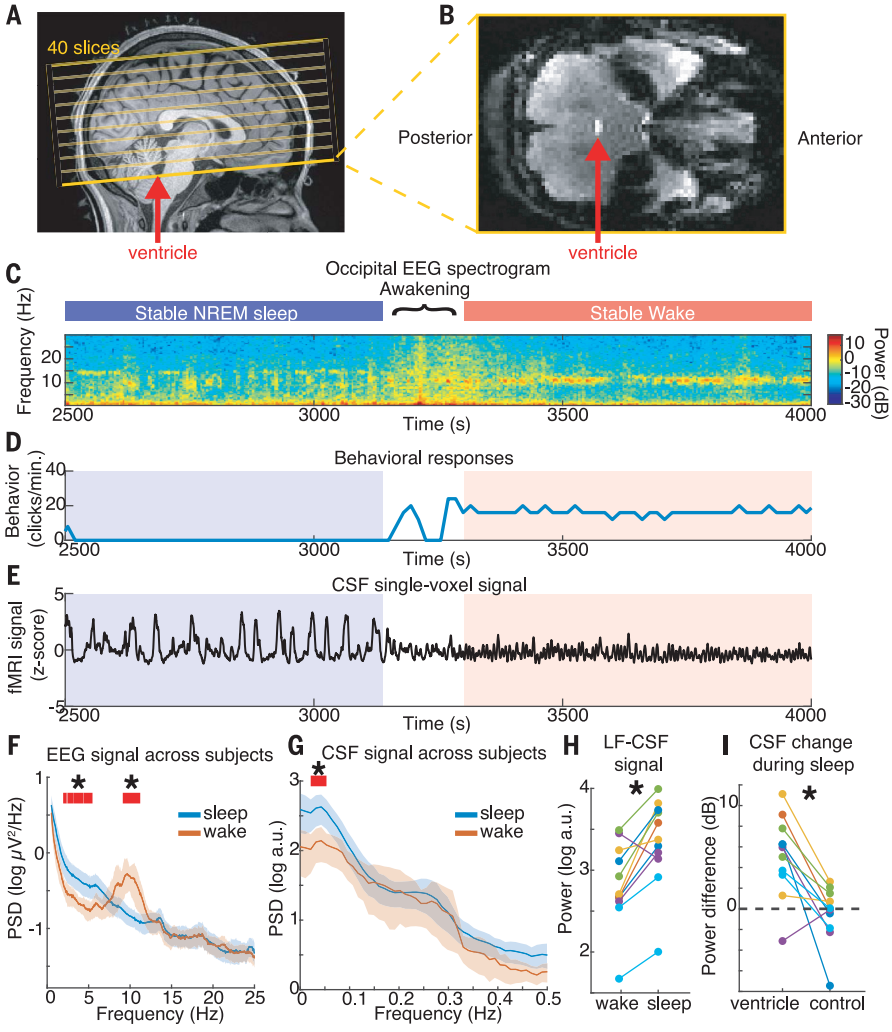

Fig. 1. Large oscillations in CSF signals appear in the fourth ventricle during sleep. (**A**) Example scan positioning. Thick yellow line: position of the functional image relative to the anatomy. The bottom edge intersects with the fourth ventricle (red arrow), allowing CSF inflow to be measured. A subset of the 40 acquired slices are displayed. (**B**) Example functional image from the bottom slice. Inflow through the ventricle is detected as a bright signal (red arrow). (**C**) EEG spectrogram from this individual shows long periods of NREM sleep and wake (~10 Hz occipital alpha). (**D**) Behavioral responses from this individual. (**E**) Time series of a single CSF voxel (smoothed with 10-TR kernel) shows large, slow dynamics in sleep that subside during wakefulness. (**F**) Mean power spectral density (PSD) of occipital EEG confirms slow-delta power in sleep, as opposed to high alpha power in wake (n = 13 participants sleep; 11 participants wake). (**G**) PSD of CSF signal shows increased 0.05 Hz power during sleep (n = 13 participants sleep; 11 participants wake). Shaded regions denote 95% CIs; red lines and asterisks mark non-overlapping CIs. (**H**) Low-frequency (LF, 0 to 0.1 Hz) CSF power increased during sleep (n = 11 participants for pairwise comparison). a.u., arbitrary units. (**I**) This sleep-selective power increase was specific to the ventricle ROI and not observed in a neighboring size-matched control ROI (n = 11 participants).

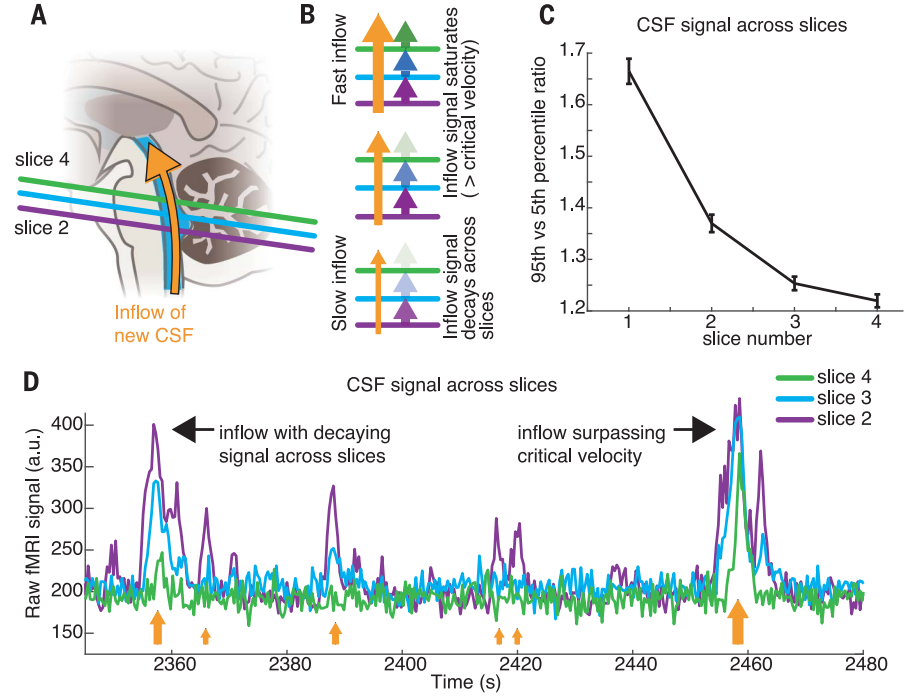

Fig. 2. Ventricle signals correspond to a ~0.05-Hz pulsatile inflow of CSF. (**A**) Schematic of acquisition. New CSF flowing into the imaging volume will generate bright signals. (**B**) Inflow signals will be largest in the bottom slice and decrease in amplitude inwards. If flow exceeds the critical velocity, then CSF in the bottom slice is completely replaced, and signal amplitudes are large in inner slices as well. (**C**) Mean amplitude across slices decays in ascending slices. Error bars are standard error across all sleep segments, with the ROI present in four contiguous slices (n = 129 segments, 11 participants). (**D**) Example time series from the bottom slices of the imaging volume in the fourth ventricle demonstrates the largest signal in the lower slices (e.g., second) and smaller signals in higher slices (e.g., fourth). Orange arrows schematically illustrate flow velocity (larger arrows denote higher velocity), and black arrows point out individual events.

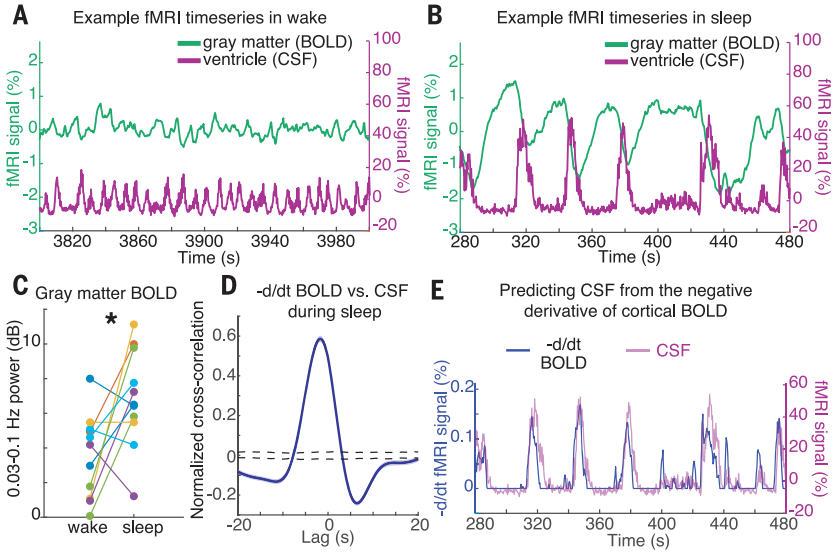

Fig. 3. CSF flow oscillations are anticorrelated to a hemodynamic oscillation in the cortical gray matter that appears during sleep, with CSF flow increasing when blood volume decreases. (**A**) Example time series of the cortical gray-matter BOLD signal and the mean CSF signal from one participant. During wake, signals are low-amplitude and synchronized to respiration (0.25 Hz). (**B**) During sleep, a large-amplitude BOLD oscillation appears, and its time course is coupled to the ventricle CSF signal (~0.05 Hz). (**C**) Mean cortical gray-matter BOLD signal power increases during sleep (n = 11 participants for pairwise test). (**D**) Mean cross-correlation between the zero-thresholded negative derivative of BOLD and CSF signals shows strong correlation (n = 176 segments, 13 participants). The shaded blue region indicates the standard error across segments; the black dashed line denotes the 95% interval of shuffled distribution. (**E**) Example time series showing the correlation, suggesting that CSF flows up the fourth ventricle when cerebral blood volume decreases.

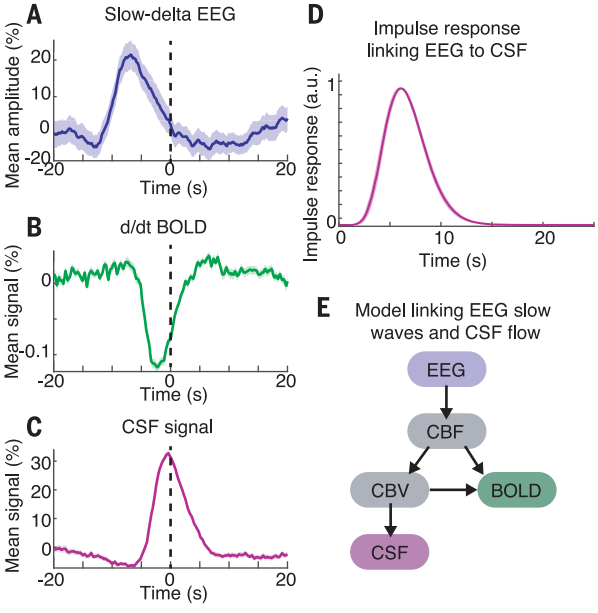

Fig. 4. EEG slow-delta waves are coupled to and precede BOLD and CSF oscillations. (**A**) Mean amplitude envelope of slow-delta EEG, (**B**) mean derivative of BOLD signals, and (**C**) mean CSF signal, all locked to the peaks of CSF waves during sleep. The shaded region represents the standard error across peak-locked trials (n = 123 peaks). (**D**) Calculated impulse response of the CSF signal to the EEG envelope shows a time course similar to that of previously established hemodynamic models. Shading indicates standard deviation across model folds. (**E**) Diagram of model linking the time course of neural activity to CSF flow. Variables include CBF and cerebral blood volume (CBV).

and found that convolving the EEG with this impulse response yielded a significant prediction of CSF dynamics (fig. S5A) (zero-lag r = 0.23, cross-validated r = 0.22 ± 0.07). To examine whether this EEG-CSF coupling was specifically linked to the appearance of CSF waves during sleep, we tested how well the EEG predicted CSF dynamics in the segments with the largest CSF waves. Performance was higher in segments with larger CSF waves (fig. S5, B and C) (zero-lag r = 0.54, P < 0.001, shuffling), suggesting that the EEG was more strongly linked to CSF in the sleep segments richest in CSF waves.

The coherent dynamics of the EEG, BOLD, and CSF signals thus exhibited a specific timing sequence, with neural rhythms preceding subsequent BOLD and CSF waves. To test whether these observed correlations and delay patterns could arise from biophysical mechanisms, we constructed a computational model using established models of hemodynamic coupling (Fig. 4E and fig. S6). We extracted the envelope of slow-delta EEG, expected to correlate with decreases in cerebral blood flow (CBF) signal because of its associated suppression of neural activity (*2*). The neural oscillation was then used to predict the time courses of blood flow, blood volume, and CSF (*33*, *34*). The model first used previously reported physiological parameters (*35*), with no additional parameter fitting, to test whether our observations were consistent with established biophysical coupling between these signals. This model performed as well as the best-fit impulse response [zero-lag R = 0.22; CI across segments = (0.16, 0.27); P < 0.001, shuffling] (fig. S6 and S7). The model prediction was significantly larger than the maximal correlation between the original EEG envelope and CSF across all lags (maximal r = 0.15, P < 0.05), demonstrating that our data were consistent with biophysical coupling between neural activity, hemodynamics, and CSF.

We conclude that human sleep is associated with large coupled low-frequency oscillations in neuronal activity, blood oxygenation, and CSF flow. Although electrophysiological slow waves are known to play important roles in cognition (*1*), our results suggest that they may also be linked to the physiologically restorative effects of sleep, as slow neural activity is followed by brain-wide pulsations in blood volume and CSF flow.

These results address a key missing link in the neurophysiology of sleep. The macroscopic changes in CSF flow that we identified are expected to alter waste clearance, as pulsatile fluid dynamics can increase mixing and diffusion (*20*, *21*, *36*). Neurovascular coupling has been proposed to contribute to clearance (*37*), but why it would cause higher clearance rates during sleep was not known. Our study suggests slow neural and hemodynamic oscillations

Downloaded from http://science.sciencemag.org/ on November 5, 2019

as a possible contributor to this process, in concert with other physiological factors. Studies in animals could next test for causal relationships between these neural and physiological rhythms.

Our identification of sleep-associated CSF fluid dynamics also suggests a potential biomarker to be explored in clinical conditions associated with sleep disturbance. Memory impairment in aging is associated with suppressed slow waves (*38*); our model suggests that this slow-wave loss would, in turn, be associated with decreased CSF flow. Furthermore, our results hint at a potential bridge between recent findings that tau CSF levels and amyloid beta depend on sleep and neural activity (*39*–*41*) and that oscillatory neural activity leads to reduced tau (*42*)—coherent neural activity might signal higher protein aggregate clearance. Taken together, our results identify waves of CSF flow that appear during sleep and show that slow rhythms in neural activity are interlinked with these CSF waves, with hemodynamic oscillations as an intermediate mechanism through which these processes are coupled.

Fluid dynamics during sleep

During non–rapid eye movement sleep, low-frequency oscillations in neural activity support memory consolidation and neuronal computation. Sleep is also associated with increased interstitial fluid volume and clearance of metabolic waste products. It is unknown why these processes co-occur and how they are related. Fultz *et al.* simultaneously measured electrophysiological, hemodynamic, and flow signals in the human brain (see the Perspective by Grubb and Lauritzen). Large oscillations of fluid inflow to the brain appeared during sleep and were tightly coupled to functional magnetic resonance imaging signals and entrained to electroencephalogram slow waves. Slow oscillatory neuronal activity thus leads to oscillations in blood volume, drawing cerebrospinal fluid into and out of the brain.

Focusing Effect of Acetylcholine on Neuroplasticity in the Human Motor Cortex

Min-Fang Kuo,[1] Jan Grosch,[1] Felipe Fregni,[2] Walter Paulus,[1] and Michael A. Nitsche[1]

[1]Department of Clinical Neurophysiology, Georg-August-University Göttingen, 37075 Göttingen, Germany, and [2]Harvard Center for Noninvasive Brain Stimulation, Boston, Massachusetts 02215

Cholinergic neuromodulation is pivotal for arousal, attention, and cognitive processes. Loss or dysregulation of cholinergic inputs leads to cognitive impairments like those manifested in Alzheimer's disease. Such dysfunction can be at least partially restored by an increase of acetylcholine (ACh). In animal studies, ACh selectively facilitates long-term excitability changes induced by feed-forward afferent input. Consequently, it has been hypothesized that ACh enhances the signal-to-noise ratio of input processing. However, the neurophysiological foundation for its ability to enhance cognition in humans is not well documented. In this study we explore the effects of rivastigmine, a cholinesterase inhibitor, on global and synapse-specific forms of cortical plasticity induced by transcranial direct current stimulation (tDCS) and paired associative stimulation (PAS) on 10–12 healthy subjects, respectively. Rivastigmine essentially blocked the induction of the global excitability enhancement elicited by anodal tDCS and revealed a tendency to first reduce and then stabilize cathodal tDCS-induced inhibitory aftereffects. However, ACh enhanced the synapse-specific excitability enhancement produced by facilitatory PAS and consolidated the inhibitory PAS-induced excitability diminution. These findings are in line with a cholinergic focusing effect that optimizes the detection of relevant signals during information processing in humans.

Key words: **neuroplasticity; acetylcholine; transcranial direct current stimulation; paired associative stimulation; motor cortex; human**

Introduction

Extensive evidence concerning cholinergic modulation of several cognitive functions supports an important role of acetylcholine (ACh) in arousal, attention, learning, and memory formation (Gold, 2003; Sarter et al., 2003). In Alzheimer's disease, enhancing cerebral ACh level has been shown to improve impaired learning and memory functions caused by cholinergic dysfunction. With regard to its specific functional properties, neurophysiological data from animal studies reveal dual neuromodulatory effects of ACh on cortical excitability and synaptic plasticity (Rasmusson, 2000; Gu, 2002). Cholinergic blockade has been shown to reduce long-term potentiation (LTP), whereas cholinergic agonists enhance LTP in the hippocampus, piriform cortex, and neocortex (Blitzer et al., 1990; Brocher et al., 1992; Hasselmo and Barkai, 1995). In humans, use-dependent plasticity of the motor cortex is facilitated by an acetylcholinesterase inhibitor and blocked by a cholinergic antagonist (Sawaki et al., 2002; Meintzschel and Ziemann, 2006). However, it is also reported that ACh enhanced long-term depression (LTD) induced with paired-pulse stimulation in the rat visual cortex (Kirkwood et al., 1999). Furthermore, it suppressed excitatory glutamatergic synaptic transmission via presynaptic inhibition at intrinsic, recurrent synapses but not afferent fiber synapses (Hasselmo and Bower, 1992; Hasselmo et al., 1995; Vogt and Regehr, 2001). This suggests a differential, activity-dependent cholinergic modification of neural networks in which ACh facilitates the detection of incoming afferent inputs, whereas it decreases intrinsic feedback excitability, thereby focusing the encoding of relevant, associated information processing (Blokland et al., 1992; Winters and Bussey, 2005).

To test the focusing action of ACh on neuroplasticity in humans, two protocols of brain stimulation were introduced in the present study. In the paired associative stimulation (PAS) protocol, repetitive peripheral nerve stimulation is paired with transcranial magnetic stimulation (TMS) of the human motor cortex (Stefan et al., 2000). It is postulated that PAS-induced excitability changes share the features of associative synaptic LTP and LTD, depending on the sequence of the near-synchronous pair of stimuli from different stimulation modalities in the motor cortex (Stefan et al., 2000; Wolters et al., 2003), which parallels the spike-timing-dependent rule for Hebbian LTP and LTD induction in animal studies (Dan and Poo, 2004). Facilitatory PAS (PAS25) with peripheral nerve stimulation applied 25 ms earlier than TMS pulse in M1 results in synchronous activation of motor cortical neurons by the afferent somatosensory stimulus and motor cortex TMS and thus enhances cortical excitability. However, inhibitory PAS (PAS10) diminishes cortical excitability with the interstimuli interval 10 ms, with which the somatosensory input reaches the motor cortex relevantly later than the TMS pulse, thereby inducing asynchronous stimulation on motor cortical neurons. PAS should specifically induce neuroplasticity in somatosensory-motor cortical synapses. In contrast, transcranial

direct current stimulation (tDCS) encompasses the global modulation of cortical network plasticity by application of weak direct currents through the surface of the scalp. Anodal tDCS enhances cortical excitability, whereas cathodal tDCS diminishes it for up to 1 h after the end of stimulation (Nitsche and Paulus, 2000, 2001; Nitsche et al., 2003a). The primary mechanism is a modulation of the resting membrane potential, and the resulting polarity-specific excitability changes subsequently induce changes of synaptic strength, which are, however, not restricted to specific synaptic connections (Bindman et al., 1964; Purpura and McMurtry, 1965). Both plasticity-inducing protocols accomplish long-lasting, NMDA receptor-dependent excitability changes (Liebetanz et al., 2002; Stefan et al., 2002; Nitsche et al., 2003b). The main difference lies in the synapse-specific focal effects of PAS: whereas the plasticity induced by tDCS is relatively nonfocal and not synapse-specific because it is thought to change cortical excitability under the whole area covered by the relatively large stimulation electrode, the plasticity induced by PAS is restricted to the intercortical connections between the somatosensory and motor cortex. According to the focusing hypothesis of ACh, it should selectively enhance and consolidate specific synaptic modifications induced by PAS, while depressing global ones accomplished by tDCS, to sharpen the signal-to-noise ratio in human cortical networks.

Materials and Methods

Subjects. Ten to twelve healthy subjects [tDCS experiment: six men, six women, aged (mean ± SD) 24 ± 3 years; PAS25 experiment: four women and six men, aged 28 ± 4 years; PAS10 experiment: 5 women and 5 men, aged 27 ± 4 years], without receiving acute or chronic medication, participated in each experiment. The groups did not differ significantly with regard to age and gender. Both studies were approved by the ethics committee of the University of Goettingen, and we conform to the Declaration of Helsinki. All subjects had given written informed consent. Because we were interested primarily in the physiological effects of ACh in this study, we recruited relatively young subjects to guarantee the comparability of the results with former pharmacological studies on neuroplasticity and to avoid including subjects with subclinical (e.g., microvascular) brain lesions, which might have influenced our results unintentionally.

Transcranial direct current stimulation. tDCS was performed with a pair of saline-soaked surface sponge electrodes (35 cm^2) with one of the electrodes placed over the representational area of the right abductor digiti minimi muscle (ADM), as determined by TMS, and the other electrode above the right orbit as reference. The currents ran continuously for 13 min (anodal tDCS) or 9 min (cathodal tDCS) with an intensity of 1 mA. In previous studies, these stimulation durations have been shown to induce aftereffects of tDCS lasting for ~1 h (Nitsche and Paulus, 2001; Nitsche et al., 2003a).

Paired associative stimulation. Peripheral nerve stimulation was applied on the right ulnar nerve at the level of the wrist with a Digitimer D185 stimulator (Digitimer, Welwyn Garden City, UK). Single-pulse TMS was delivered over the representing area of the right ADM. Each TMS pulse, at an intensity eliciting a muscle evoked potential of ~1 mV peak-to-peak amplitude, was preceded by an ulnar nerve stimulus with an interval of 25 ms (PAS25) or 10 ms (PAS10) using a standard stimulation block (cathodal proximal) at a stimulation width of 200 μs and stimulation intensity of 300% of the perceptual threshold, defined as the lowest intensity of the stimuli that is perceivable by the subject. Ninety pairs were applied at 0.05 Hz over 30 min, which has been shown to induce long-lasting excitability changes in the motor cortex (Stefan et al., 2000).

Pharmacological interventions. Rivastigmine (3 mg) or equivalent placebo drugs were taken by the subjects 2 h before the start of the intervention (Kennedy et al., 1999). This dose was chosen to minimize drug-induced side effects, but to enhance the cholinergic level of the CNS effectively. The experimental sessions were performed in a randomized order and were separated by at least 1 week to avoid cumulative drug or stimulation effects.

Measurement of motor cortical excitability. TMS-elicited muscle-evoked potentials (MEPs) were recorded to measure excitability changes of the representational motor cortical area of the right ADM. Single-pulse TMS was conducted by a Magstim 200 magnetic stimulator (Magstim Company, Whiteland, Dyfed, UK) with a figure-eight-shaped magnetic coil (diameter of one winding, 70 mm; peak magnetic field, 2.2 tesla). The coil was held tangentially to the skull, with the handle pointing backward and laterally at an angle of 45° from midline. The optimal position was defined as the site at which stimulation resulted consistently in the largest MEPs. Surface EMG was recorded from the right ADM with Ag-AgCl electrodes in a belly-tendon montage. The signals were amplified and filtered with a time constant of 10 ms and a low-pass filter of 2.5 kHz and then digitized at an analog-to-digital rate of 5 kHz and further relayed into a laboratory computer using the Signal software and CED 1401 hardware (Cambridge Electronic Design, Cambridge, UK). The intensity was adjusted to elicit baseline MEPs of, on average, 1 mV peak-to-peak amplitude and was kept constant for the poststimulation assessment unless adjusted (see below).

Experimental procedures. The experiments were conducted in a repeated measurement design. For the tDCS experiment, a complete crossover design was chosen. For the PAS experiments, separate subject groups participated in the PAS10 and PAS25 experiments. Subjects were seated comfortably in a reclining chair. First the optimal position of the magnetic coil for eliciting MEPs in the resting ADM was assessed over the left motor cortex, and 20 MEPs were recorded for the first baseline. Two hours after intake of the medication, a second baseline was determined to control for a possible influence of the drug on cortical excitability and adjusted if necessary. Subjects were not aware about and could not distinguish between the specific stimulation protocols used, nor were they informed about the medication administered in a specific session.

In experiment 1 with tDCS, one of the DC electrodes, to which in the following the terms cathodal or anodal tDCS refer, was fixed at the cortical representational area of ADM as defined during the first baseline recording, and the other one was fixed at the contralateral forehead area above the right orbit. Direct currents were applied on 12 subjects for 9 min (cathodal) or 13 min (anodal). After cessation of tDCS, 20 MEPs were recorded at 0.25 Hz every 5 min for half an hour and then every 30 min until 2 h after the end of DC stimulation, because tDCS-induced aftereffects without medication will not last longer than this period of time (Nitsche and Paulus, 2000; Nitsche et al., 2003a). Because of the relatively diurnal stability of corticospinal excitability, we did not expect additional excitability changes after MEPs returned to baseline level again. Only for the rivastigmine conditions, TMS recordings were performed at four additional time points: same day evening, next morning, next noon, and next evening.

In experiment 2 with PAS, the interventional PAS protocol as described above was used on 10 subjects. TMS recording procedures were the same as described above.

Data analysis and statistics. MEP amplitude means were calculated first individually and then interindividually for each time bin including both baseline values. The postintervention MEPs were normalized and are given as ratios of the baseline determined immediately before intervention (tDCS/PAS).

In the tDCS experiment, a repeated-measure ANOVA for the time bins up to 120 min after tDCS was calculated with the within-subject factors time course, current stimulation (anodal and cathodal tDCS), drug condition (rivastigmine vs placebo), and the dependent variable MEP amplitude. For PAS experiment, we performed a repeated-measure ANOVA with PAS (PAS25 and PAS10) as between-subject factor and within-subject factors drug condition (rivastigmine vs placebo) and time course for MEPs up to 120 min after intervention. If appropriate, *post hoc* Student's *t* tests (paired samples, two-tailed, $p < 0.05$, not adjusted) were performed to determine whether the MEP amplitudes before and after the interventional brain stimulations differed in each intervention condition and whether those differences depended on the drug conditions.

Table 1. Results of the ANOVAs

	Parameters	df	*F* value	*p* value
Experiment 1 (tDCS)	TDCS	1	40.585	< 0.001*
	Drug	1	3.650	0.082
	Time course	10	1.700	0.099
	tDCS × drug	1	3.417	0.092
	tDCS × time course	10	1.868	0.066
	Drug × time course	10	0.290	0.976
	tDCS × drug × time course	10	4.206	< 0.001*
Experiment 2 (PAS)	PAS	1	73.006	< 0.001*
	Drug	1	0.140	0.712
	Time course	10	1.556	0.123
	Drug × PAS	1	23.886	< 0.001*
	Time course × PAS	10	9.934	< 0.001*
	Drug × time course	10	2.207	0.019*
	Drug × time course × PAS	10	3.208	0.001*

In both experiments, the ANOVAs encompass the time course up to 120 min after tDCS or PAS, because the remaining time points were only measured for the rivastigmine conditions. "Drug" represents rivastigmine and placebo, whereas "tDCS" indicates anodal and cathodal polarity, and "PAS" represents PAS25 and PAS10. $p \leq 0.05$.

Additional *post hoc* tests (Student's *t* tests, $p < 0.05$) were performed to explore whether rivastigmine modified baseline MEPs.

Results

Three subjects experienced prominent side effects under rivastigmine (nausea, vomiting, and dizziness) and were excluded from the experiment. Two of the participating subjects complained about slight nausea after taking rivastigmine, but the symptoms subsided before the neuroplasticity-inducing intervention. Baseline MEP amplitudes did not differ significantly before and after drug intake in all conditions. Absolute baseline MEP amplitudes were not different in all medication and stimulation subgroups (Student's *t* tests, paired, two-tailed, $p > 0.05$).

Effects of rivastigmine on tDCS-induced motor cortex excitability shifts (experiment 1)

The ANOVA revealed a significant main effect of tDCS ($F = 40.585$; $p < 0.001$) and tDCS × drug × time course ($F = 4.206$; $p < 0.001$) (Table 1). In the PLC conditions, the anodal tDCS-induced excitability increase stayed significant until 30 min after tDCS, and the cathodal tDCS-induced inhibition lasted until 60 min after DC stimulation. As revealed by the *post hoc t* tests (paired, two-tailed, $p < 0.05$), rivastigmine initially abolished the induction of both the anodal tDCS-elicited excitability enhancement and the cathodal tDCS-elicited excitability diminution. However, a delayed, consolidated inhibition induced by cathodal tDCS was observed in the rivastigmine condition, compared with placebo conditions. The decrease of excitability generated by cathodal tDCS under rivastigmine remained significant for 2 h after tDCS, whereas it returned to baseline level after 60 min in the PLC condition (Fig. 1).

Effects of rivastigmine on PAS-induced motor cortex excitability shifts (experiment 2)

The ANOVA displayed a significant main effect of PAS ($F = 73.006$; $p < 0.001$). The interactions between drug × PAS ($F = 23.886$; $p < 0.001$), time course × PAS ($F = 9.934$; $p < 0.001$), drug × time course ($F = 2.207$; p 0.019), and drug × time course × PAS ($F = 3.208$; $p < 0.001$) were also significant (Table 1). In the PAS25 experiment, the excitatory shift of MEP amplitudes returned to baseline 25 min after PAS in the placebo medication condition, as revealed by Student's *t* tests (paired, two-tailed, $p < 0.05$), whereas rivastigmine enhanced and prolonged the excitatory effects of PAS25 (Fig. 2). In the PAS10 experiment, the inhibitory effect without medication lasted for half an hour. Rivastigmine further enhanced and prolonged the inhibition until the same day evening after intervention (Fig. 3).

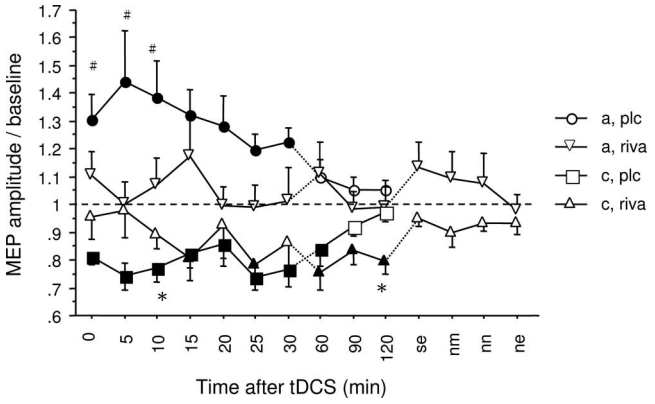

Figure 1. Cholinergic modulation of global cortical plasticity induced by tDCS. Rivastigmine abolished the induction of anodal tDCS-elicited excitability increases, as recorded by TMS-evoked MEP amplitudes. Additionally, rivastigmine initially diminished the excitability reduction induced by cathodal tDCS under rivastigmine. However, the respective excitability diminution was later consolidated. Filled symbols indicate significant deviations from baseline with regard to each drug condition. Hash symbols indicate significant differences in anodal tDCS-induced excitability changes between placebo and rivastigmine conditions; asterisks represent significant differences in inhibition caused by cathodal stimulation between the placebo and rivastigmine medication conditions (Student's *t* test, two-tailed, repeated measures; $^{\#}p < 0.05$). a, Anodal; c, cathodal; plc, placebo; riva, rivastigmine; se, same evening; nm, next morning; nn, next noon; ne, next evening. Error bars indicate SEM.

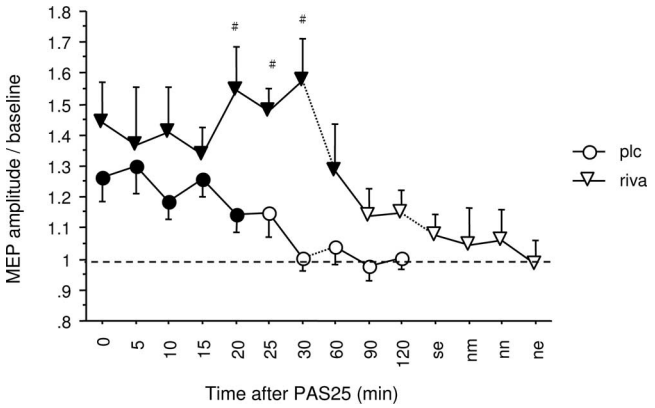

Figure 2. The PAS25-induced synapse-specific excitability enhancement is facilitated by ACh. The PAS-induced excitability enhancement was increased and prolonged under rivastigmine until 30 min after PAS, whereas MEP amplitudes returned to baseline 25 min after PAS in the placebo condition. Hash symbols represent significant differences between placebo and rivastigmine conditions; filled symbols indicate significant deviations from baseline with regard to each drug condition (Student's *t* test, two-tailed, repeated measures; $^{\#}p < 0.05$). plc, Placebo; riva, rivastigmine; se, same evening; nm, next morning; nn, next noon; ne, next evening. Error bars indicate SEM.

Discussion

The present study demonstrates that ACh enhances the synapse-specific cortical excitability increase induced by PAS25 and consolidates the PAS10-induced reduction of motor cortical excitability, whereas it prevents global excitatory aftereffects produced by anodal tDCS. ACh also delayed the induction of the cathodal tDCS-elicited excitability decrease and slightly prolonged its overall duration. Because MEP amplitudes were not modified by rivastigmine in the dosage applied alone, we have no evidence for a direct cholinergic influence of the drug on corticospinal excit-

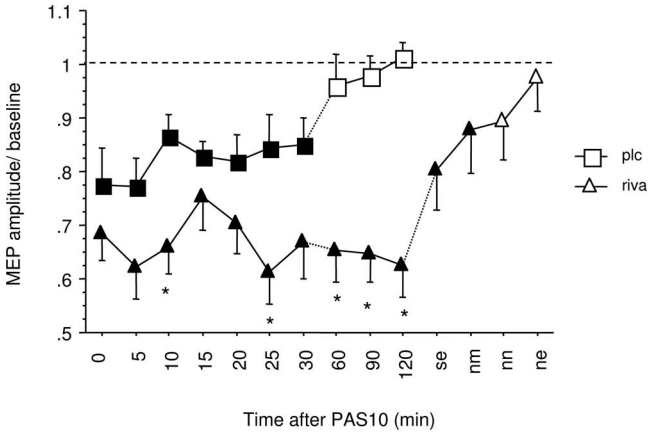

Figure 3. The PAS10-induced synapse-specific excitability diminution is consolidated by ACh. In the placebo condition, the inhibitory effect of PAS10 lasted for approximately half an hour, whereas rivastigmine enhanced the inhibition and further prolonged it until same day evening of the intervention. Significant differences between placebo and rivastigmine are shown with asterisks. Filled symbols indicate significant deviations from baseline with regard to each drug condition (Student's *t* test, two-tailed, repeated measures, $p < 0.05$). plc, Placebo; riva, rivastigmine; se, same evening; nm, next morning; nn, next noon; ne, next evening. Error bars indicate SEM.

ability. The results support the hypothesis of a focusing effect of ACh on neuroplasticity of cortical networks. ACh not only increased selectively the efficacy of synapse-specific excitability-enhancing neuroplasticity, but also prolonged the excitability diminution in case of asynchronous synapse-specific inputs and suppressed global excitability enhancements. By these mechanisms, ACh is well suited to improve the signal-to-noise ratio and to refine information processing in neural networks.

ACh diminishes tDCS-driven neuroplasticity

At first glance, the inhibitory effect of rivastigmine on facilitatory neuroplasticity induced by anodal tDCS seems contradictory to the results obtained from animal studies in which LTP was facilitated by cholinergic stimulation (Brocher et al., 1992; Abe et al., 1994; Hasselmo and Barkai, 1995; Patil et al., 1998). The major conceptual difference between these studies and our tDCS experiment is the manipulation applied for neuroplasticity induction. In slice preparation, the plastic changes induced with either paired or high-frequency suprathreshold electrical stimulation are caused by synchronous activation of synaptic connections. In contrast, tDCS-elicited neuroplasticity is a consequence of increasing general, asynchronous network activity, possibly added by modification of the postsynaptic resting membrane potential (Bindman et al., 1964; Purpura and McMurtry, 1965). The diminution of the anodal tDCS-induced excitability enhancement might thus be because of an ACh-induced decrease of general excitation within global neuronal networks, probably modulated via the cholinergic presynaptic inhibition of excitatory feedback potentials or excitatory transmission at recurrent connections. Moreover, evidence reveals that the suppression of synaptic transmission is selective for recently modified synapses (Linster et al., 2003) but does not apply to silent synapses (Fernandez de Sevilla et al., 2002). Thus it is probable that synapses that are globally modified by tDCS in the present study are more susceptible to cholinergic suppression of synaptic transmission during plasticity induction. A similar effect is also demonstrated by a recent study using a dynamic clamp system to mimic *in-vivo*-like background activities in motor cortical slices, in which cholinergic facilitation of LTP was attenuated in the presence of random background noise (Desai and Walcott, 2006).

However, ACh revealed a tendency to consolidate excitability-diminishing aftereffects generated by cathodal tDCS, although it abolished its initial induction phase. The biphasic effect of rivastigmine on cathodal tDCS-induced plasticity can also be explained by a cholinergic regulation of different neurons within different temporary profiles. The initial blockade could be because of the fast negative modulation of inhibitory neurons (e.g., inhibitory interneurons) known to be induced by ACh (Ji and Dani, 2000), whereas the late-onset and prolonged excitability diminution can be explained by the inhibitory modification of excitatory neurons with the combination of ACh and cathodal tDCS. Further studies are required to test this hypothesis.

Cholinergic consolidation of PAS-induced cortical plasticity

The PAS experiment demonstrates a positive cholinergic modulation of PAS-elicited synaptic-specific plasticity. ACh seems to enhance specifically the ability of synchronous motor cortical input to enhance excitability, whereas the excitability diminution accomplished by asynchronous input is prolonged. It is suggested that PAS25/PAS10 relates to associative LTP/LTD in the human motor cortex (Stefan et al., 2000, 2002; Wolters et al., 2003; Stefan et al., 2006). Because ACh has been shown to facilitate cortical sensory plasticity by enhancing sensory input processing (Rasmusson and Dykes, 1988; Tremblay et al., 1990; Patil et al., 1998) and suppressing irrelevant input (Hasselmo and Barkai, 1995), one might further speculate that rivastigmine specifically improved the efficacy of PAS by (1) enhancing the signal-to-noise ratio, thereby facilitating meaningful information processing as represented by synchronous input; and (2) suppressing non-meaningful input as represented by asynchronous stimulation within neural networks.

Thus, the results of our study are in accordance with the respective animal experiments (Blitzer et al., 1990; Hasselmo and Barkai, 1995; Kirkwood et al., 1999). Moreover, they are concordant with the results of recent behavioral studies in the human motor cortex exploring the effect of ACh modulation on use-dependent plasticity, which was blocked by the ACh antagonist scopolamine (Sawaki et al., 2002) and enhanced by an acetylcholinesterase inhibitor (Meintzschel and Ziemann, 2006). Therefore, our results offer a neurophysiological mechanism of how ACh might improve behavioral plasticity.

It is also notable that the duration of cholinergic effects on cortical plasticity induced by PAS25 and PAS10 is asymmetric. ACh was more effective in stabilizing the PAS10-generated excitability reduction than the PAS25-induced excitability enhancement. This might be because of the generally less efficient PAS25 protocol, as revealed in the placebo condition in the present study, which might have limited the ability of ACh to stabilize neuroplasticity. Alternatively, it was suggested that the direction of cholinergic modulation on synaptic plasticity could be determined by ACh concentration and subtype receptors activation (Kuczewski et al., 2005), which could also explain an asymmetry of ACh effects on different PAS protocols.

Summary of cholinergic modulation in human cortical plasticity

The results of the present study suggest that ACh has fairly specific effects on cortical plasticity. Rivastigmine selectively enhanced the efficacy of PAS25, a synchronous associative stimulation protocol, to increase excitability, whereas it shifted the effects of the remaining plasticity-inducing protocols in an inhib-

itory direction. This indicates a general inhibitory effect of rivastigmine on network excitability, with the exception of PAS25-induced plasticity, and further explains how rivastigmine works as a cognitive enhancer via increasing the signal-to-noise ratio of cortical activity. Associative plasticity is suggested as a neurophysiological correlate of learning and memory formation, and, indeed, excitability-enhancing PAS has been shown to be tightly connected to learning processes (Ziemann et al., 2004; Stefan et al., 2006), thus strengthening the efficacy of synchronous stimuli to enhance excitability might improve learning. However, rivastigmine can reduce "noisy" synaptic modification, as demonstrated in our study via abolishing the excitability-enhancing properties of anodal tDCS, which increases general and most probably not synchronous cortical activity (Bindman et al., 1964; Purpura and McMurtry, 1965), and via strengthening the inhibitory effects of the asynchronous PAS10 protocol. Moreover, rivastigmine enhanced the efficacy of cathodal tDCS to diminish cortical excitability. Cathodal tDCS applied synchronously with PAS25 has been shown to enhance the efficacy of PAS25 to increase cortical excitability (Nitsche et al., 2007), which can be explained by a noise-reducing function of cathodal tDCS-induced inhibition. Thus the enhancing effect of rivastigmine on cathodal tDCS-driven inhibition should also increase the efficacy of meaningful information processing via increasing the signal-to-noise ratio.

A recently conducted study revealed similar effects of L-dopa (L-3,4-dihydroxyphenylalanine) on neuroplasticity (Kuo et al., 2007). Here, dopamine reversed the anodal tDCS-induced excitability enhancement into inhibition and prolonged the excitability diminution caused by cathodal tDCS. However, dopamine enhanced the PAS25-induced synapse-specific increase of cortical excitability. The similarity of the dopamine and ACh effects could be explained by the fact that dopaminergic and cholinergic neurons serve similar functions and are tightly interconnected in neuronal networks (Sarter et al., 1999; Zahm, 2006). They also provide, at least, a theoretical option for the application of dopamine in neurological disorders associated with cognitive deficits. Indeed, dopaminergic medication has been shown to improve learning in healthy subjects and patients after stroke (Floel et al., 2005, 2007).

Together, the results of the present study are in line with cortical cholinergic functions enhancing the contrast of relevant stimuli against background noise or distractors, thereby improving signal processing during information encoding. Therefore, it might strengthen the rational basis for application of cholinesterase inhibitors to improve cognitive functions in patients with Alzheimer's disease or vascular dementia. However, it has to be kept in mind that the results were obtained with healthy young subjects. Further studies are needed to elucidate whether the effect of ACh on neuroplasticity is identical in elderly healthy and demented patients and whether the impact of ACh on neuroplasticity is correlated with clinical outcome.

PET Imaging of Dopamine D2 Receptors in Monkey Models of Cocaine Abuse: Genetic Predisposition Versus Environmental Modulation

Michael A. Nader, Ph.D.

Paul W. Czoty, Ph.D.

Objective: Animals self-administer many of the drugs that humans abuse, including cocaine. This article describes studies using preclinical animal models to differentiate the influences of neurobiological predisposition from environmental modulation of cocaine addiction, including studies from the authors' laboratory using nonhuman primates.

Method: Addiction is described in terms of vulnerability, maintenance, and abstinence. This review focuses on dopamine receptor function, in particular that of the D2-like receptors, as measured by the noninvasive imaging procedure positron emission tomography. Findings from human studies of addiction and animal models are reviewed.

Results: There appears to be an inverse relationship between D2 receptor availability and vulnerability to the reinforcing effects of cocaine. Environmental variables can increase or decrease D2 receptor binding in an orderly fashion, and the resulting changes in D2 function influence the vulnerability to abuse cocaine. In maintenance, chronic cocaine exposure produces decreases in D2 receptor binding, which may be a mechanism that contributes to continued drug use. Finally, during abstinence there are individual differences in rates of recovery of D2 receptor availability.

Conclusions: The goal of the preclinical research described in this review is to achieve a better understanding of individual differences in susceptibility and vulnerability to the reinforcing effects of cocaine. It is clear that the development of novel animal models will extend our understanding of the neurobiological basis of drug addiction to include a greater appreciation of the role of environmental factors in affecting predisposition, mediating continued drug use, and triggering relapse.

(Am J Psychiatry 2005; 162:1473–1482)

Recent estimates indicate that the number of new cocaine users per year more than doubled from 1992 (0.5 million) to 2002 (1.1 million) (1). From 1994 to 2001, visits to hospital emergency rooms that involved cocaine increased by 22% (2). Despite more than three decades of research into the molecular, cellular, and behavioral effects of cocaine, no pharmacotherapy for cocaine abuse has demonstrated sufficient safety and effectiveness for widespread clinical use (3, 4). As astutely pointed out by Leshner (5), most people see drug abuse and addiction as a social problem, and as such, the problem is frequently handled only with social solutions, in particular through the criminal justice system. Recent reports indicate that the 40%–60% of people seeking treatment are ordered to do so by the courts or corrections system (see reference 6), suggesting that treatment does not occur until drug use has led to substantial adverse consequences to the individual. However, if drug addiction is viewed as a brain disease, then addiction should be amenable to treatments, just as depression, schizophrenia, and anxiety are treatable. As Leshner stated,

> Understanding addiction as a brain disease explains in part why historic policy strategies focusing solely on the social or criminal justice aspects of drug use and addiction have been unsuccessful. They are missing at least half of the issue. If the brain is the core of the problem, attending to the brain needs to be a core part of the solution. (5, p. 47)

In response to growing evidence, the World Health Organization recently issued a report focusing on the role of the brain in mediating drug dependence (7). The goal of the present review is to highlight some of the brain imaging studies of cocaine abuse with a special emphasis on the use of animal models to help us understand the human condition.

Use of Brain Imaging Techniques in Cocaine Abuse Research

Cocaine is an indirectly acting monoamine agonist, binding to the dopamine, serotonin, and norepinephrine transporters (8, 9). The majority of research on cocaine has involved the dopamine system, which will be the focus of this review. Cocaine binds to the dopamine transporter and blocks uptake of dopamine from the synapse. The elevated levels of dopamine activate two superfamilies of dopamine

receptors, D1- and D2-like. This review will focus on D2-like receptors, which have been intimately linked to drug abuse (for instance, see references 10–12). The positron emission tomography (PET) studies that we will describe involve radiotracers that do not differentiate among subtypes of the D2 superfamily (i.e., D_2, D_3, and D_4 receptor subtypes).

To study the brain, powerful imaging techniques have been developed that allow for the noninvasive exploration of brain function in humans and in animals. In this review, we will highlight studies utilizing PET. A clear strength of PET is the ability to examine the brain repeatedly in longitudinal studies. PET has been described as a functional measure of brain activity because it records the uptake and washout of a radioactive marker that competes with endogenous neurotransmitters (13). For example, the radiotracers [^{11}C]raclopride and [^{18}F]fluoroclebopride bind to D2-like receptors with similar affinities. The primary dependent variable in PET imaging studies is the ratio of the distribution of radioligand in the region of interest compared to its distribution in a region devoid of receptors. This ratio, termed the distribution volume ratio, provides a unitless number representing the ratio of receptor density (B_{max}) to receptor affinity. In theory, changes in the distribution volume ratio noted in longitudinal studies reflect changes in B_{max}. However, changes in the distribution volume ratio may also reflect changes in extracellular dopamine levels. Increases in extracellular dopamine will decrease radioligand binding, whereas decreases in extracellular dopamine will increase radioligand binding (for example, see references 13–15). Thus, in addition to being affected by the actual number of receptors in the tissue, the binding of these radioligands is influenced by the amount of dopamine present in the synapse. As a result, when we describe PET data, we use interchangeably "binding" and "availability," since both are being assessed.

In contrast to PET imaging studies, in vitro receptor autoradiography provides a measure of receptor density in a particular brain structure that is not influenced by the levels of a neurotransmitter. The limitation, however, is that the procedures are terminal and, consequently, only one time point can be studied. These are important considerations for longitudinal PET studies because the possibility that changes in PET measures are due to changes in neurotransmitter levels rather than the density of receptors cannot be ruled out unless additional studies are conducted. In this review, we attempt to address this issue by also describing in vitro studies using receptor autoradiography procedures in which circulating dopamine levels are not influencing receptor density assessments.

Animal Models of Drug Abuse: One of the Most Powerful Models of Human Disease

One strategy implemented by the National Institute on Drug Abuse is the development of novel animal models to better understand the neurochemical mechanisms mediating the high abuse potential of cocaine. A greater understanding of the neuropharmacology of cocaine will ultimately lead to improved treatment for cocaine dependence. Animal models of drug self-administration have proven to be valid predictors of human drug abuse (3, 16–20). Animals will self-administer most of the drugs that humans abuse, including cocaine, alcohol, nicotine, and heroin, by the routes (intravenous, inhaled, and oral) used by humans (17). More recently, these models have been extended to examine behavioral and physiological responsiveness to environmental variables as indicators of vulnerability to drug use (21). In one of the earliest studies on individual differences and vulnerability to drug abuse, Piazza et al. (22) initially characterized rats' behavior in an open-field apparatus on the basis of how much locomotor activity was observed prior to any drug exposure. They found that rats characterized as "high responders" in an open field had higher basal corticosterone levels and were more likely to self-administer *d*-amphetamine than rats characterized as "low responders." Consistent with this characterization, noncontingent electric foot shock, which increased corticosterone levels in rats, facilitated acquisition of cocaine self-administration (23). In other experiments, bilateral adrenalectomy or administration of metyrapone, which blocks corticosterone synthesis, completely abolished the acquisition of cocaine self-administration (24). Thus, it appears that individual differences in vulnerability to drug abuse can be observed in animal models and that these differences may be due, in part, to stress-hormone responsiveness.

In addition, animal models of drug abuse have begun to incorporate more sophisticated designs, including the inclusion of alternative reinforcers and the study of cocaine choice, that may provide greater validity than models that simply examine the reinforcing effects of drugs (see references 25–27). For example, when monkeys are given a choice between food and cocaine, there is a dose-dependent relationship between drug dose and preference (see, for instance, references 26–28). That is, when low cocaine doses are the alternative to food, monkeys choose food; at higher cocaine doses, a monkey's preference shifts to almost exclusively cocaine choices. Manipulations of environmental variables can increase or decrease cocaine choice. For example, increases in the magnitude of the nondrug alternative (i.e., food reinforcement) decrease cocaine choice. Similarly, increases in the response requirement for cocaine (analogous to increases in the cost of the drug) decrease cocaine choice (26, 27, 29). The converse is also true: increases in the cost of the preferred nondrug alternative increase the frequency with which cocaine is chosen (26, 27, 29).

These results emphasize that drug reinforcement is not simply mediated by actions in the brain but that the environment can alter drug reinforcement and, as we will show, brain function. A growing body of preclinical re-

search supports the hypothesis that environmental stressors can enhance and environmental enrichment can attenuate the reinforcing effects of drugs. This hypothesis has clear implications for clinical outcomes. As we will discuss, these environmental stimuli affect brain function, including processes mediated by dopamine receptors. Compared to enrichment, more work has focused on the role of stress in drug abuse (see reference 30), with stressors including foot shock or more ethologically relevant variables such as social stress and social defeat. We will describe studies that utilize a novel animal model of drug abuse in which male monkeys live in social groups and have access to cocaine daily.

To relate the preclinical findings to a more global goal of translational research, it is important to point out several advantages of the animal models highlighted in this article. First, drugs can have different effects on brain function depending on whether they are administered by the investigator or self-administered by the animal (31, 32). Because we are interested in studying addictive *behavior,* drug self-administration has face validity as an animal model of a human condition. Second, in our studies of nonhuman primates we also examine complex social behaviors and stable individual behavioral characteristics (e.g., aggressive and affiliative behaviors in particular) that closely model human social interactions (see reference 33). In macaque monkeys, the formation of social hierarchies is determined by the outcome of physical confrontations (i.e., fights). The monkey that wins all of the fights in the social group is the most dominant, the monkey that wins all encounters except with the most dominant animal is the monkey ranked number 2, and so forth. This hierarchy is transitory and linear, such that if number 2 wins a battle with number 3 and number 3 is ranked above number 4, then number 2 is above number 4. We view the linear hierarchy that forms, with the dominant monkeys at the top and the subordinate animals at the bottom, as a continuum from environmental enrichment at one end to high levels of stress at the other. Socially derived stressors have high ethological validity with regard to the study of human drug abuse. Finally, nonhuman primates have many advantages over other animal species. There is abundant evidence that rodent and primate brains differ in the anatomy, physiology, and neurochemistry of brain dopamine systems (34–37). Furthermore, the nonhuman primate brain differs substantially from the rodent brain in terms of cocaine-induced changes in brain metabolism (38, 39). Nonhuman primates can be studied in long-term experiments with cocaine self-administration (over years) that use within-subject designs, and they are capable of learning complex behaviors in order to obtain drugs. The use of PET imaging to examine neuroadaptations allows for longitudinal examination of brain changes due to environmental and/or pharmacological manipulations (e.g., references 40–42). The studies described in the following sections will focus on three phases of drug addiction: vulnerability, maintenance, and abstinence/relapse.

Relation of D2 Receptor Binding to Vulnerability to Cocaine Abuse

Perhaps one of the most challenging issues in drug abuse research involves understanding the etiology of addiction. Epidemiological studies suggest that approximately 17% of the people who use cocaine become dependent on the drug (43, 44). Studies in humans can generate hypotheses about potential brain markers that may indicate a predisposition to become addicted. For example, Volkow et al. (45) studied 23 non-drug-abusing male subjects and used the dopamine transport inhibitor methylphenidate as a tool to study stimulant abuse. First, each subject was scanned with the D2 receptor ligand [^{11}C]raclopride. On another day, they were administered 0.5 mg/kg of methylphenidate and asked to complete an analogue self-rating scale for pleasant drug effects. Approximately one-half (N=12) of the 23 subjects reported liking the dose of methylphenidate, while nine of them described it as "unpleasant" (two were indifferent to the drug effect). Subjects who found methylphenidate "pleasant" had significantly lower levels of D2 receptor binding than subjects who reported the drug as "unpleasant." While these findings suggest an inverse relationship between D2 receptor availability and "vulnerability" to stimulant reinforcement, because of ethical concerns humans cannot be studied prior to drug exposure and then allowed to self-administer the drug for an extended period of time. Animal models, however, can be used to test hypotheses generated from studies of human drug abusers.

We explored further the relationship between D2 receptors and sensitivity to psychostimulants in a novel model of drug abuse in monkeys housed together (40). Previous work from our group had shown a relationship between D2 receptor availability, as measured with PET, and the social rank of female monkeys (46). Subordinate monkeys had significantly lower levels of D2 receptor binding than dominant monkeys. This relationship between social rank and D2 receptors generated an interesting series of questions related not only to drug abuse but also to trait theory. Our first question was whether D2 receptor availability influenced social rank. That is, were monkeys genetically predisposed to a particular position in the social hierarchy according to basal D2 receptor availability? To answer this question, we studied 20 individually housed male monkeys by using the D2 receptor ligand [^{18}F]fluoroclebopride (47) before the monkeys were housed together. The level of D2 receptor binding determined during individual housing did not predict eventual social rank. That is, D2 availability was not a trait variable influencing dominance hierarchies (40).

The next question was whether formation of the social hierarchies influenced D2 receptor availability. When

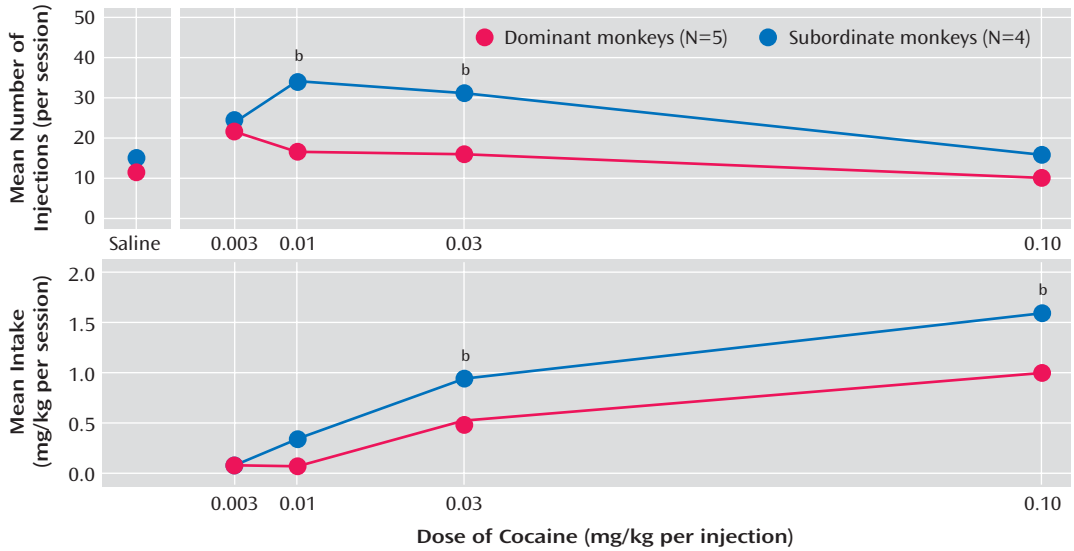
TABLE 1. Relation of Dopamine D2 Function to Social Rank in Monkeys While Individually Housed and Again After Social Group Formation[a]

	Distribution Volume Ratio (B_{max}/K_d) From PET Study With [^{18}F]Fluoroclebopride					
	Individual Housing		Social Housing		% Change	
Social Rank	Mean	SE	Mean	SE	Mean	SE
Dominant (N=5)	2.49	0.08	3.04	0.23	22.0	8.8
Subordinate (N=5)	2.40	0.06	2.49	0.10	3.9	5.3

[a] The data were originally presented by Morgan et al. (40) in *Nature Neuroscience* (http://www.nature.com/neuro) and are reprinted with permission of Nature Publishing Group.

these animals were rescanned after 3 months of social housing, there were significant differences between groups, with the subordinate monkeys having significantly lower D2 receptor binding than the dominant monkeys (40). This finding replicated our earlier work with female monkeys (46) and extended it to males. However, when we compared each monkey's [^{18}F]fluoroclebopride distribution volume ratio when they were individually housed to the new ratio after social group formation, a profound effect was noted: the average distribution volume ratios for dominant monkeys increased by over 20%, while those for the subordinate animals were nearly unchanged from their original baselines (Table 1). These results suggest that becoming the dominant monkey in the social group produced large changes in dopamine receptor function.

One hypothesis that could account for the observed changes is that being the dominant monkey is analogous to living in an enriched environment. Dominant animals have access to treats in the pen, they are groomed more often than subordinate monkeys, and they move about freely (33). Enrichment could affect the PET signal (i.e., produce increases in the distribution volume ratio) by increasing D2 receptor densities and/or decreasing levels of extracellular dopamine in dominant monkeys. Studies using rodents have clearly shown that environmental enrichment can affect dopamine neurotransmission in an orderly and reliable fashion consistent with both potential mechanisms. For example, Bowling et al. (48)) examined the effects of different rearing environments on dopamine synthesis and metabolism in rats. The group in the "enriched" condition lived together, with 12 or 13 rats per cage, and was exposed to novel toys. Another group lived under "impoverished" conditions consisting of individual housing without toys in the cage. In vitro studies indicated that the rats in the enriched condition had lower striatal concentrations of dopamine than the rats in the impoverished condition. In another study, Hall et al. (49) used in vivo microdialysis to compare rats reared in isolation with socially reared rats, and they found that dopamine levels in the nucleus accumbens were higher in the isolation-reared rats than in the socially reared rats. Furthermore, D2 receptor densities were lower in the isolation-reared rats than in the socially reared rats (49). These findings clearly show that environmental variables as seemingly subtle as housing conditions can produce profound changes in the functional status of dopamine systems. Overall, the findings in rodents are in the same direction as the effects we observed after formation of social groups by monkeys.



An important question is whether these environmentally induced brain changes have behavioral consequences. In particular, how do these variables influence vulnerability to drug abuse? If, as previously noted in humans, there is a relationship between D2 receptor availability and stimulant reinforcement, then there should be differences in drug reinforcement between dominant and subordinate monkeys and subordinate animals should be more sensitive to the effects of cocaine. This is, in fact, what we found (40). When subsequently allowed access to cocaine, subordinate animals self-administered cocaine at higher rates and had larger intakes than those for dominant monkeys (Figure 1). Overall, these findings confirmed an inverse relationship between D2 receptor availability and cocaine reinforcement and suggested that environmental variables could affect brain function and vulnerability to cocaine abuse.

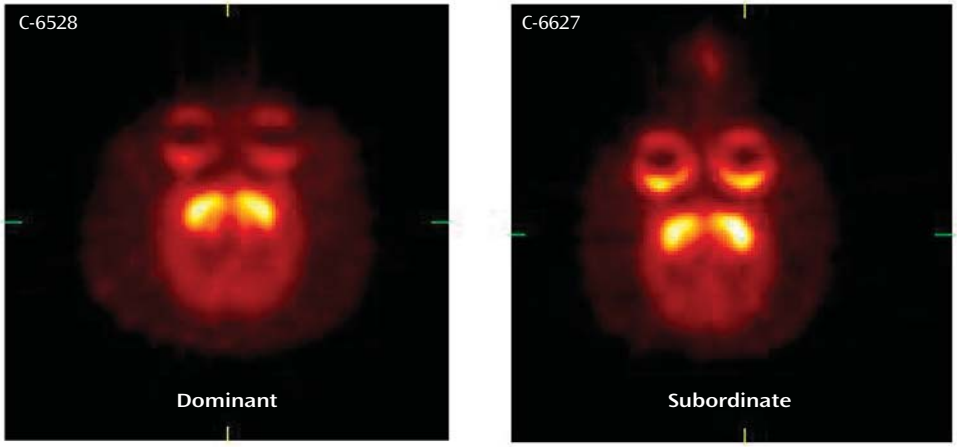
Decrease of D2 Receptor Binding With Continued Cocaine Use

Human PET imaging studies have shown lower D2 receptor availability in cocaine abusers than in age-matched comparison subjects (11). However, as already described, it is not clear whether the lower D2 receptor binding was a predisposing trait or a consequence of cocaine exposure (see reference 11). Understanding how long-term cocaine exposure affects dopamine receptor function could ultimately lead to better treatment strategies. One hypothesis is that D2 receptor down-regulation occurs as an adaptation to the chronic elevation in extracellular dopamine due to chronic blockade of dopamine uptake. A strength of using animal subjects is the ability to study drug-naive subjects and to observe changes in receptor availability with exposure to a drug by means of a within-subjects, longitudinal design (see reference 50, for example).

We recently extended our studies of socially housed monkeys to examine the effects of chronic cocaine exposure in dominant and subordinate monkeys (51). Whereas dominant monkeys were initially protected from the reinforcing effects of cocaine by elevated D2 availability, chronic exposure to self-administered cocaine resulted in D2 measures that were no longer different from those of subordinate monkeys (Figure 2). These findings suggested that exposure to cocaine attenuated or reversed the powerful effects of environmental context on dopamine receptor availability. Studies utilizing in vitro receptor autoradiography of D2 receptors have consistently shown lower receptor densities in monkeys with long-term his-

FIGURE 1. Relationship of Cocaine Self-Administration to Social Rank in Monkeys[a]

[a] The values are averages from the last 3 days that each dose was available for self-administration. The data are adapted from an article by Morgan et al. (40) in *Nature Neuroscience* (http://www.nature.com/neuro) and are reprinted with permission of Nature Publishing Group.
[b] Significantly different from value for dominant group ($p<0.05$).



tories of cocaine self-administration; many of these effects were directly related to dose and duration of exposure (52–54).

A central issue for this phase of addiction is one that was raised for the first phase, namely individual differences. For example, one issue to consider in addition to the dose of a drug taken in the lifetime of the individual is the pattern and duration of drug use. Volkow et al. (11) noted that there was not a relationship between D2 receptor binding and the dose of cocaine used, but there was a significant correlation between D2 binding and duration of cocaine use. The effects of duration and cocaine intake can be addressed with animal models in which cocaine availability is the primary independent variable. The question could be phrased as, Does administering a large amount of cocaine over a short period of time produce greater long-term effects on dopamine receptor function than does administering moderate doses over longer periods? In a study not utilizing cocaine self-administration, in vitro receptor autoradiography was used to assess the consequences of chronic cocaine use and abstinence on D2 receptor levels (55). Monkeys were treated four times per day with cocaine for 2 consecutive weeks, followed by a 2-week withdrawal period. The investigators found no differences between cocaine-treated and control monkeys in D2 receptor densities in the caudate nucleus, prefrontal cortex, substantia nigra, and nucleus accumbens. However, this amount of cocaine administered has since been shown to produce robust decreases in D2 receptor densities when *self-administered* over longer periods of time (see, for instance, references 52 and 53). Such findings suggest that the duration of exposure is as important as the actual dose of drug administered and reinforce the importance of using contingent drug administration in animal models of addiction. Future studies using in vivo imaging techniques will better address this extremely important question.

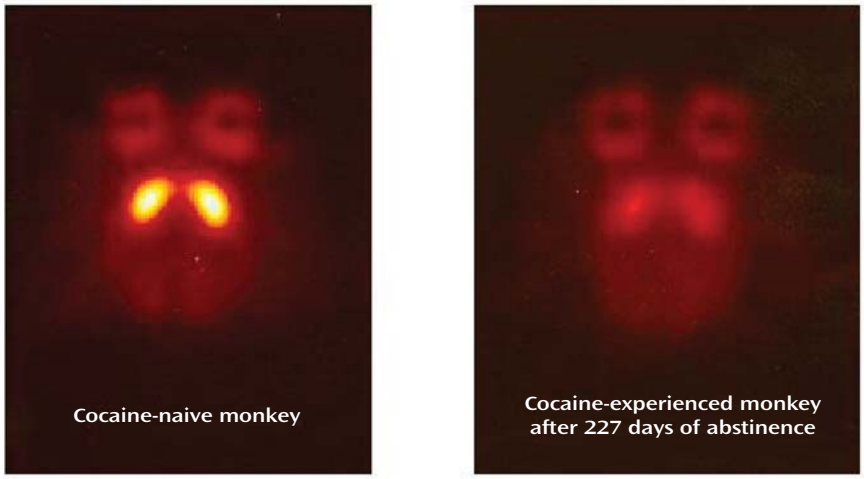
As we discussed for the vulnerability phase, an important question is whether there are functional consequences to cocaine-induced changes in D2 receptor binding. Of particular interest are issues related to cognitive function, decision making, and choice behavior. For example, Grant et al. (56) compared a group of drug abusers (opiate and/or stimulant) and non-drug-abusing comparison subjects on a series of neuropsychological tests to examine the long-term consequences of drug use on decision making. In one set of studies, subjects were exposed to the "gambling task" (57), which has strong face validity for evaluating cognitive deficits (56). The task involved four different decks of cards that differed along three dimensions: immediate gain, long-term expected gain, and schedule of penalties. Two of the four decks had smaller gains and punishers but higher overall "yields"; the comparison subjects chose from those decks most often. In contrast, the majority of the drug abusers chose from the low-yield decks, indicating poor decision making. To control for possible differences in IQ, Grant et al. (56) also used the Wisconsin Card Sorting Test and found no differences between the groups. The authors concluded that impairments in decision making could certainly account for continued use of drugs in the presence of adverse social and personal consequences.

Studies with cocaine abusers cannot clarify whether such cognitive impairments are a consequence of excessive cocaine use or reflect preexisting decrements that predispose certain individuals to drug abuse. Animal studies

FIGURE 2. PET Images of [^{18}F]Fluoroclebopride in Dominant and Subordinate Monkeys With Extensive Histories of Cocaine Self-Administration[a]

[a] The images were coregistered with MRIs from the same monkeys and are shown at the level of the striatum (caudate and putamen). From experiments described by Czoty et al. (51).

can address this issue. Using our model with group-housed monkeys, we studied choice behavior involving cocaine and a nondrug reinforcer—banana-flavored pellets (27). Subordinate monkeys were more sensitive to the reinforcing effects of cocaine than were dominant monkeys. That is, subordinate monkeys chose cocaine over food at a lower cocaine dose than that for dominant monkeys. Such findings suggest that environmental context can substantially influence the preference to choose drug over nondrug alternatives even when D2 binding does not differ between groups.



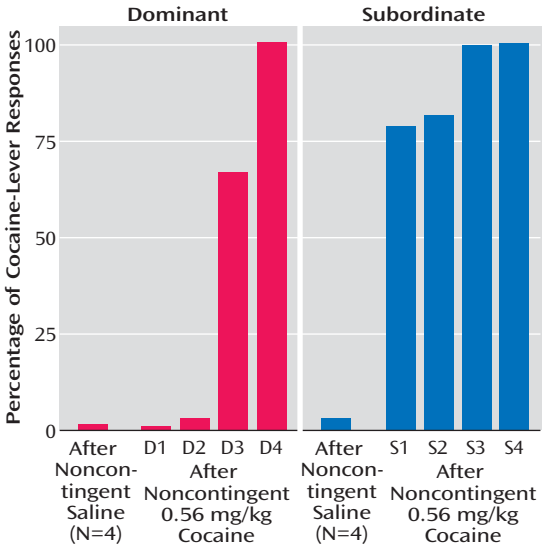
Variable Recovery of D2 Receptor Binding During Cocaine Abstinence

The final phase of drug addiction to be discussed is abstinence and the variables that influence relapse. As with vulnerability and maintenance, we will focus on dopamine D2 receptor availability. From a clinician's viewpoint, abstinence is the critical phase because the population seeking professional guidance and treatment are in this phase; it is worth pointing out that this is the phase of drug addiction about which we know and understand the least. The preceding issues related to vulnerability (predisposition) and maintenance (i.e., changes in brain function due to chronic drug exposure) are critical in understanding brain changes associated with abstinence. However, understanding these variables may provide only a glimpse of the complexity involved in brain changes during abstinence. Perhaps Childress et al. stated it best: "This search [for a cocaine medication] has been complicated by the heterogenous target: drug desire that emerges during cocaine cessation…may well have a different brain substrate than desire induced by cocaine itself…and the cues that signal it" (58, p. 11).

Over a decade ago, Volkow and colleagues (59) reported significantly lower D2 receptor binding in cocaine abusers abstinent from cocaine for up to 4 months. These reductions in D2 receptor binding were associated with decreased glucose utilization in the orbitofrontal cortex and with self-ratings of dysphoria (11). Thus, there was an association between dopamine receptor availability and negative subjective effects during abstinence. The study ended 4 months after the start of abstinence because all subjects had relapsed. Animal models, on the other hand, can provide valuable insight into the neuropharmacology of abstinence and relapse because abstinence can be studied for years.

Our first efforts to study D2 receptor function during abstinence involved using PET imaging to compare D2 receptor binding in monkeys with extensive histories of cocaine self-administration and cocaine-naive comparison monkeys (i.e., a group design). For example, the first monkey we studied had self-administered cocaine for over 3 years and had a lifetime cocaine intake of approximately 20 g. PET scans were conducted at various time points during abstinence. Differences in [^{18}F]fluoroclebopride binding between this cocaine-experienced monkey and a cocaine-naive monkey were apparent at all time points and, as shown in Figure 3, did not dissipate even after 7 months of abstinence. The image from a comparison monkey shows excellent uptake of [^{18}F]fluoroclebopride into D2-rich regions of the basal ganglia. In the abstinent cocaine-experienced monkey, D2 receptor binding was more than 20% lower. While it is possible that the lower D2 signal in the cocaine-experienced monkey was due to elevated levels of dopamine, it is unlikely that such an effect would persist for 7 months. The other possibility is that chronic cocaine exposure resulted in persistent reductions in D2 receptor densities. This hypothesis has been

FIGURE 3. PET Images of [18F]Fluoroclebopride in Cocaine-Naive and Cocaine-Experienced Monkeys[a]



[a] Images are shown at the level of the basal ganglia. From an unpublished study by M.A. Nader and R.H. Mach.

confirmed by means of in vitro receptor autoradiography (52, 53; see reference 54 for further discussion).

It is necessary to comment on animal models and "craving." As defined by Hommer, craving "is a term derived from popular psychology that is used to describe one of the mental states—namely, the intense desire for a certain object or experience" (60, p. 187). Assessing a mental state in an animal is not a realistic undertaking. However, we can measure behavior and hypothesize about mental states. Describing the multitude of animal models of craving is beyond the scope of this review. In brief, the strategies can involve persistence of drug seeking in the presence of stimuli that signal no drug is available (61), escalation of drug seeking with changes in drug availability (62), responding in the presence of conditioned stimuli (63), or a return of responding that had been previously extinguished (i.e., reinstatement) (64).

The reinstatement procedure has been widely used as a model of the ability of priming injections of drugs, drug-related cues, and stress to precipitate relapse into drug taking (reviewed in reference 65). Although the predictive and construct validity of the procedure remain to be firmly established (66), the ability of noncontingent administration of cocaine to reinstate extinguished responding previously maintained by cocaine has been well established (65). Furthermore, it has been demonstrated that drugs that directly or indirectly activate the dopamine system can reinstate cocaine seeking under a food-drug choice procedure (67). Thus, the reinstatement procedure allowed us another means to assess potential differences in dopamine receptor function between dominant and subordinate monkeys. Socially housed monkeys were allowed to self-administer cocaine under conditions in which they also could choose food reinforcement. Under these conditions, as the cocaine dose increased, the percentage of total responses involving the cocaine-associated lever increased (27). When saline was substituted for cocaine, the

FIGURE 4. Effect of a Noncontingent Cocaine Injection on Individual Dominant (D1–D4) and Subordinate (S1–S4) Monkeys' Responses on a Lever Previously Associated With Cocaine but Currently Producing Saline Injections[a]

[a] The first bar for each group represents the average injection-lever responding following noncontingent saline injection. A significant difference was observed after noncontingent injection of 0.56 mg/kg cocaine between the dominant and subordinate monkeys. The data are from an unpublished study by P.W. Czoty, C. McCabe, and M.A. Nader.

monkeys shifted their responses to the food-associated lever (Figure 4). We next examined the ability of noncontingent cocaine to reinstate responses on the cocaine-associated lever, although these responses continued to produce saline injections. Noncontingent cocaine produced dose-related increases in responses on the cocaine-associated lever at doses up to 0.30 mg/kg in all monkeys (data not shown). However, dominant and subordinate monkeys differed in their responses to a higher cocaine dose (0.56 mg/kg). All four subordinate monkeys responded prima-

rily on the injection lever following this dose of cocaine (Figure 4). Greater variability was observed in the dominant monkeys' responses to this dose. These data are consistent with our earlier results demonstrating that subordinate monkeys are, on average, more sensitive to the reinforcing strength of cocaine and/or less sensitive to the aversive effects of cocaine than are dominant monkeys.

Conclusions

In this review we have attempted to briefly highlight the use of animal models and brain imaging procedures (PET and in vitro receptor autoradiography) to convey a better understanding of the neuropharmacology of drug addiction. The focus on dopamine D2 receptors can be viewed as a strength as well as a limitation. The strength of this focus is the understanding of how the level of this receptor superfamily serves as a trait influencing vulnerability to drug abuse and how it serves as a potential state variable showing malleability as a result of environmental or pharmacological manipulations. The weakness of this focus on D2 receptors is the fact that drug addiction is not mediated by one receptor subtype. Future studies must examine how other neurotransmitter and neurohormone systems change in concert with brain dopamine systems, as well as the development of novel radioligands for specific receptor subtypes (e.g., D_3 receptors). In addition, increased anatomical selectivity with higher-resolution PET cameras will better address the contribution of particular brain circuitry to behavioral effects.

The use of animal models to study human disease is an extremely important tool. We have described models that could be characterized as predictive, isomorphic, and homologous of the human condition. In particular, the use of socially housed nonhuman primates to better understand the neuropharmacology and the behavioral and social consequences of drug abuse and to evaluate potential treatment strategies has unequivocal potential. It is our hope that clinicians reading this review will gain a better understanding of the research questions being asked and the potential importance of the results for the development of therapies (behavioral and pharmacological) for drug addiction.

Finally, this review has provided evidence that the environment can profoundly affect drug abuse vulnerability, maintenance, and relapse. Environmental stress and enrichment can influence brain function and vulnerability to drug abuse. Furthermore, even following long-term drug use, environmental variables can affect the behavioral effects of cocaine. The research described in this review represents the growing number of studies documenting the benefits of environmental enrichment, irrespective of genetic predispositions to abuse drugs. Such preclinical findings suggest that outcome measures will be enhanced not only by taking individuals out of a stressful environment but also by providing alternative reinforcers—whether these are better living conditions, jobs, or other activities (68).

Genetic Influences on Sociability: Heightened Amygdala Reactivity and Event-Related Responses to Positive Social Stimuli in Williams Syndrome

Brian W. Haas,[1]* Debra Mills,[2]* Anna Yam,[3] Fumiko Hoeft,[1] Ursula Bellugi,[3] and Allan Reiss[1]

Williams syndrome (WS) is a genetic disorder caused by a hemizygous microdeletion on chromosome 7q11.23. WS is associated with a compelling neurocognitive profile characterized by relative deficits in visuospatial function, relative strengths in face and language processing, and enhanced drive toward social engagement. We used a combined functional magnetic resonance imaging (fMRI) and event-related potential (ERP) approach to examine the neural basis of social responsiveness in WS participants to two types of social stimuli, negative (fearful) and positive (happy) emotional facial expressions. Here, we report a double dissociation consistent across both methods such that WS participants exhibited heightened amygdala reactivity to positive (happy) social stimuli and absent or attenuated amygdala reactivity to negative (fearful) social stimuli, compared with controls. The fMRI findings indicate that atypical social processing in WS may be rooted in altered development of disparate amygdalar nuclei that subserve different social functions. The ERP findings suggest that abnormal amygdala reactivity in WS may possibly function to increase attention to and encoding of happy expressions and to decrease arousal to fearful expressions. This study provides the first evidence that the genetic deletion associated with WS influences the function of the amygdala to be particularly responsive to socially appetitive stimuli.

Key words: **Williams syndrome; genetics; fMRI; emotions; amygdala; ERP**

Introduction

Studying the neural basis of social cognition in individuals with well defined genetic etiologies advances our understanding of how genes influence social behavior. Williams syndrome (WS) is a genetic condition caused by a hemizygous microdeletion on chromosome 7q11.23. Individuals with WS are characterized by a distinctive neuropsychological profile comprised of deficient visuospatial function (Meyer-Lindenberg et al., 2004), relative strengths in language (Mervis and Becerra, 2007) and face (Mobbs et al., 2004; Santos et al., 2008) processing, and a tendency for enhanced affiliative drive (Jones et al., 2000; Doyle et al., 2004). For example, those with WS are less socially inhibited (Doyle et al., 2004), more likely to rate emotional facial expressions as approachable (Frigerio et al., 2006), and more gregarious (Klein-Tasman and Mervis, 2003) than mentally aged control groups. Although enhanced drive for social interaction in Williams syndrome has been reported using several experimental (Bellugi et al., 1999; Jones et al., 2000; Mervis and Klein-Tasman, 2000; Klein-Tasman and Mervis, 2003; Deutsch et al., 2007) and cross-cultural (Zitzer-Comfort et al., 2007) approaches, the neural basis of social cognitive function in WS remains poorly understood.

One brain region known to be involved in social functions such as affiliative processes is the amygdala (Skuse et al., 2003). The amygdala codes for the social/emotional salience of both negatively and positively valenced information (Costafreda et al., 2008; Paton et al., 2006), and damage to this structure results in profound abnormalities in social functioning (Aggleton, 2000). Indeed, previous studies have reported functional abnormalities of the amygdala in WS. For example, compared with typically developing controls, WS individuals exhibit diminished amygdala response to fearful stimuli (Meyer-Lindenberg et al., 2005) and heightened amygdala response to music (Levitin et al., 2003). It is unknown, however, if individuals with WS exhibit functional abnormalities when processing positively valenced social/emotional stimuli such as happy facial expressions. Is this study, we tested the hypothesis that those with WS exhibit heightened amygdala response to socially appetitive (happy) stimuli and diminished amygdala response to negative (fearful) social stimuli. We chose to measure amygdala function by means of two complementary methods, functional magnetic resonance imaging (fMRI) and event-related potentials (ERPs), using identical stimuli and a similar experimental design. fMRI provides the opportunity to spatially localize differences in activation during each

condition, while ERP provides the opportunity to more accurately dissociate temporal components during each condition. Based on reports that those with WS are relatively hypersocial (Doyle et al., 2004) and have a particular affinity toward happy facial expressions (compared with mentally aged controls) (Frigerio et al., 2006), we predicted that we would observe heightened amygdala response during the processing of happy facial expressions in WS compared with controls. Additionally, based on findings demonstrating that those with WS exhibit reduced amygdala response to fearful social stimuli (Meyer-Lindenberg et al., 2005), we predicted that we would observe a similar pattern as assessed by both fMRI and ERP.

Materials and Methods

Participants. Twenty-seven subjects [13 typically developing (TD), 5 males; and 14 WS, 7 males] participated in the fMRI study, and seventy subjects [25 TD, 11 males; 30 WS, 11 males; and 15, 8 males with developmental delay (DD) of unspecified etiology] participated in the ERP study. Eleven subjects with WS [4 males, mean (M) = 31.13, SD = 7.55] participated in both fMRI scanning and ERP recording. Subjects were excluded from participating if they had a history of psychiatric or neurologic problems as assessed by the Symptom Checklist-90-R (SCL-90-R) (Derogatis, 1977). All included subjects had SCL-90-R scores that fell within one SD of a normative sample. Subjects were also excluded if they reported any current use of mood-altering medication, substance abuse during the 6 months before scan or any standard MRI contraindications.

WS participants were recruited as part of an ongoing multicenter collaborative research study focused on investigating the functional neuroanatomy of WS (33 total; 13 males; mean age = 31.01; SD = 8.80). The diagnosis of WS was genetically confirmed in all participants using the fluorescent *in situ* hybridization test for a deletion of one copy of the elastin gene on chromosome 7. TD subjects were recruited locally (Palo Alto, CA for fMRI and San Diego, CA for ERPs) and were financially compensated for their participation [38 total; 18 males; M = 29.71; SD = 9.52; intelligence quotient (IQ): M = 106, SD = 11.8]. DD participants were recruited locally (San Diego, CA) through community media and state-run agencies (total 15; 8 males; M = 28.07, SD = 8.8; IQ: M = 62, SD = 8.8). Criteria for participation in the DD group included developmental delay of unknown etiology without the presence of symptoms indicative of an autism spectrum disorder. This study was approved by the Stanford University and Salk Institute Administrative Panel on Human Subjects in Medical Research

There were no significant differences in age ($F_{(2,67)} = 0.600$, $p = 0.552$) or proportion of males to females between the groups ($\chi^2_{(2)} = 1.155$, $N = 70$, $p = 0.561$). The WS and DD groups were matched on full-scale IQ (WS: M = 65, SD = 6.8; DD: M = 62, SD = 8.8; $t_{(43)} = 1.148$, $p = 0.153$).

Task design. The stimuli consisted of color pictures of headshots of young adults displaying happy, fearful, and neutral expressions. One hundred undergraduate students were trained to display emotional expressions depicting a variety of emotional expressions including happy, fearful, and neutral. Each photograph was rated by 20 students on a five-point Likert scale for how typical each photograph depicted each emotional category with 1 scored as "not at all like the emotion" and 5 scored as "very characteristic of the emotion." Only stimuli that had the highest average ratings for a given target emotion were selected for that category. Fearful face stimuli were rated as more fearful than neutral ($t = 16.01$, $p < 0.001$) and happy ($t = 18.65$, $p < 0.001$) faces, neutral face stimuli were rated as more neutral than fearful ($t = 36.63$, $p < 0.001$) and happy ($t = 47.54$, $p = 0.001$) faces, and happy face stimuli were rated as more happy than fearful ($t = 61.93$, $p < 0.001$) and neutral ($t = 49.66$, $p < 0.001$) faces. A group of randomly selected photographs were selected to create scrambled isoluminant images that were divided into 256 parts as in a previous study (Mobbs et al., 2004).

Both the fMRI and ERP tasks were event-related designs with four experimental conditions (happy, fearful, neutral, and scrambled) and a resting baseline. Subjects were instructed to judge if each face was male, female, or scrambled by responding with their right index, middle, or ring finger as quickly and as accurately as possible. In the fMRI task, there were a total of 30 trials per condition. Each stimulus was presented for 1750 ms, followed by a 250 ms duration fixation cross. There were two runs, with each run lasting 4 min 32 s. In the ERP task, there were a total of 50 trials per condition. Each stimulus was presented for 1750 ms, followed by a 250 ms duration fixation cross. The intertrial interval was random with a mean of 1000 ms (range = 800–1200 ms). The random order of the intertrial interval was determined by using Presentation software (Neurobehavioral Systems). Behavioral responses were collected within the 2000 ms following the onset of each stimulus in both the fMRI and ERP task.

fMRI data acquisition. Whole-brain imaging data were acquired on a GE-Signa 3 T scanner (General Electric). For structural whole-brain images, a three-dimensional high-resolution spoiled gradient scan (SPGR) (repetition time, 24 ms; echo time, 5 ms; flip angle, 15°; number of excitations, 2; matrix size, 256 × 256; field of view, 24 cm; slice thickness, 1.2 mm; 124 contiguous slices) and a T1 in-plane scan (14 slices, 5 mm thickness; oriented parallel to the line between the anterior and posterior commissure) were conducted. Functional images were acquired using a gradient echo T2*-weighted echoplanar imaging scan and were obtained using a flip angle of 80°, repetition time = 2.0 s, echo time = 30 ms, 32 slices, and a field of view = 200 × 200 mm matrix.

Functional data were preprocessed and statistically analyzed using SPM2 (Wellcome Department of Imaging Neuroscience, London, UK). The images were temporally realigned to the middle slice and spatially realigned to the first in the time series. The images were then coregistered and spatially normalized into standard stereotactic space (MNI template). All images were spatially smoothed with an 8 mm full width-half maximum isotropic Gaussian filter.

ERP data acquisition. The electroencephalogram was recorded using a high-density 64-channel geodesic net from Electrical Geodesics and sampled at 250 Hz, with a bandpass of 0.1–100 Hz. The electrooculogram was recorded from over and under the left eye to monitor blinks and vertical eye movements and from the right outer canthus to monitor horizontal eye movements. Impedances were maintained below 50 kΩ. The averaged ERPs were also digitally filtered off-line with a 30 Hz low-pass filter. All electrodes were referenced to the vertex during recording and rereferenced off-line to the average of the left and right mastoids for analysis. Artifact rejection was conducted off-line using an automatic computer program to reject trials containing blinks and vertical and horizontal eye movements (±70 μV). A mean of 88% of the trials (mean = 44/50 trials per condition, SD = 7.06) for the TD group, 70% (35/50 trials, SD = 12.71) for the WS group, and 64% (32/50 trials, SD = 11.05) for the DD group were retained for analysis. The WS group had fewer artifact-free trials per condition than the TD group main effect of group ($F_{(1,53)} = 10.00$, $p = 0.003$) but did not differ from the DD group ($F_{(1,43)} = 0.601$, $p = 0.443$). Two additional participants with WS, one TD, and one DD had <10 trials for a given condition and were excluded from the analysis.

fMRI data analysis. Fixed-effects models representing two runs for each participant were used at the individual subject level of analysis and random effects models were used for group-level analyses (SPM2). At the individual level, models were created that represented all event-related task conditions (happy, fearful, neutral, scrambled, and fixation). Each stimulus presentation was modeled as a single event. Data were high-pass filtered. Images identified to correspond with >2 mm of motion were not included in the statistical analysis. There was no significant difference in the number of images excluded between groups (TD average = 0.15; WS = 0.50). Images were not excluded if they corresponded with incorrect responses.

Statistical analyses were initiated by performing a condition-by-group (2 × 2) interaction analysis. This was conducted by using a random effects model comparing the difference in blood oxygenation level-dependent (BOLD) signal during each emotional condition (happy or fearful) versus neutral between experimental groups (WS vs TD). The simple effects within each experimental group were then explored by comparing BOLD signal change between each of the emotional conditions (happy or fearful) versus neutral.

Based on previous studies reporting atypical amygdala function in WS (Meyer-Lindenberg et al., 2005) and previous studies reporting changes

in amygdala function during the processing of positive social stimuli (Canli et al., 2002; Skuse et al., 2003; Paton et al., 2006; Costafreda et al., 2008), we designated the amygdala as an a priori region of interest (ROI). The delineation of the left and right amygdala ROIs were based on Talairach definitions in standard stereotactic space (http://www.fmri.wfubmc.edu). Unless otherwise specified, we used a $p < 0.05$ statistical threshold (corrected for multiple comparisons within the amygdala) for this analysis. Event-related responses were extracted from significant clusters within the amygdala using a moving average for each time course of 200 ms. Percentage signal change between conditions was calculated based on the difference of the peak response extracted from each cluster during either happy or fearful conditions compared with neutral.

ERP data analysis. Numerous studies have identified ERP components sensitive to emotional content, including the components measured here: an N200 linked to arousal and attention (Streit et al., 1999; Sato et al., 2001; Balconi and Lucciari, 2007), an anterior positivity linked to valence (Dolcos and Cabeza, 2002), and a posterior positivity linked to arousal and/or increased subsequent memory for emotional stimuli (Diedrich et al., 1997; Dolcos and Cabeza, 2002; Eimer and Holmes, 2007; Koenig and Mecklinger, 2008). Based on the current data and previous studies, ERP emotion effects were measured using mean amplitudes for the N200 between 200 and 280 ms, the anterior positivity from 500 to 700 ms, and the posterior positivity from 300 to 500 ms. A peak latency measure was also taken for the N200 between 200 and 280 ms. As the distributions of these emotion effects varied over the scalp, the electrodes used in the statistical analysis differed for each ERP component (supplemental Fig. 1, available at www.jneurosci.org as supplemental material). Trials were not excluded if they corresponded with incorrect responses.

Group comparisons of the difference waveforms for happy − neutral and fearful − neutral for the N200, P300–500, and P500–700 were analyzed in repeated-measures ANOVAs using SPSS 13 with three levels of group (WS, TD, and DD) as the between-subjects variable, two levels of hemisphere (left and right), and electrode site (number is variable according to the montage) as repeated measures. The happy versus neutral comparison was conducted over central posterior sites, and thus there was no comparison across hemisphere. Planned comparisons for each group analyzed separately were conducted for each component with two levels of emotion (e.g., happy vs neutral, or fearful vs neutral), two levels of hemisphere for fearful versus neutral, and electrode site (same sites as used in the group analyses). The Greenhouse-Geisser correction was used for main effects and interactions with more than one electrode site. To control for differences between men and women in the effects of emotion on brain activity, preliminary analyses included gender as a separate between-subjects factor in the ANOVA. There were no interactions with emotion and gender for any of the groups; therefore, gender was not included as a factor in the analyses reported below.

Results

Behavioral measures

Mean reaction times and accuracy were submitted to a general linear model of repeated measures with subject group (WS, TD, and DD) and experimental condition (happy, fearful, neutral, and scrambled) entered as factors. Overall, WS subjects (mean reaction time: 1222.66) responded slower compared with TD subjects (796.03) ($F = 46.61$, $p < 0.001$) but not DD (1377.66) subjects ($F = 1.35$, $p = 0.25$). Similarly, WS (88.33% accuracy) subjects were less accurate in identifying gender than TD (97.36% accuracy) ($F = 0.15.47$, $p < 0.001$) subjects, but not DD (88.97%) subjects ($F = 0.03$, $p = 0.87$). Participants in each group and in each study (fMRI and ERP) were cognizant of all task instructions and performed the task above a threshold for accuracy of 75%. There was no between-group effect in the difference between reaction time (RT) or accuracy during either of the emotional conditions (RT: happy: $t = -0.73$; $p > 0.10$; fearful: $t = 0.55$; $p > 0.10$; accuracy: happy: $t = -0.56$; $p > 0.10$; fearful: $t = 1.36$; $p > 0.10$) compared with the neutral condition (condition × group interaction).

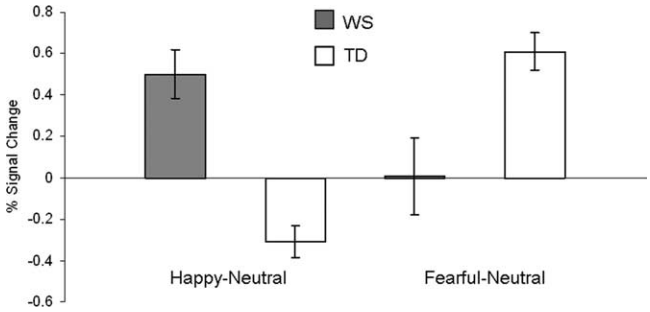

Figure 1. Right amygdala activation to happy (left) and fearful (right) facial expressions compared with neutral between groups. Bars represent percentage signal change of clusters localized by means of direct comparisons between the TD and WS groups. Error bars represent SEM.

Amygdala reactivity to happy facial expressions

We compared happy relative to neutral amygdala response between the two experimental groups (condition × group interaction). Relative to TD participants, the WS group exhibited greater right amygdala reactivity to happy compared with neutral facial expressions ($p < 0.05$ corrected; 28 voxels; MNI: 30, 0, −14) (Fig. 1, left). On the other hand, the TD group did not exhibit significantly greater left or right amygdala reactivity to happy compared with neutral facial expressions than the WS group. We next compared BOLD signal within the amygdala during the response to happy and neutral facial expressions in the WS and TD groups independently (Fig. 2). The WS group exhibited significant right amygdala reactivity to happy compared with neutral facial expressions ($p < 0.05$ corrected; 16 voxels; MNI: 32, −2, −14) (Fig. 2*B*). This cluster encompassed a relatively superior region ($z = -14$) within the standardized amygdala ROI. No significant left or right amygdala activation in response to happy compared with neutral facial expressions was observed in the TD group.

Amygdala reactivity to fearful facial expressions

We compared fearful relative to neutral amygdala response between the two experimental groups (condition × group interaction). Relative to WS participants, the TD group exhibited greater right amygdala reactivity to fearful compared with neutral facial expressions at a level approaching statistical significance ($p = 0.064$ corrected, $p = 0.002$ uncorrected, two voxels; MNI: 20, 0, −14) (Fig. 1, right). To explore the consistency of our findings with that of a previous study (Meyer-Lindenberg et al., 2005), we also compared amygdala response to fearful expressions relative to "nonsocial" stimuli (scrambled faces). Relative to the WS group, the TD group exhibited greater right amygdala reactivity to fearful compared with scrambled faces at the corrected statistical threshold ($p < 0.05$ corrected, 19 voxels; MNI: 24, −2, −16). There was no significant difference in amygdala reactivity to neutral relative to scrambled faces between the WS and TD groups. Additionally, the WS group did not exhibit significantly greater left or right amygdala reactivity to fearful (compared with either neutral or scrambled) facial expressions than the TD group. We next compared BOLD signal within the amygdala during the response to fearful and neutral facial expressions in the TD and WS groups independently (Fig. 2). The TD group exhibited significant right amygdala reactivity to fearful compared

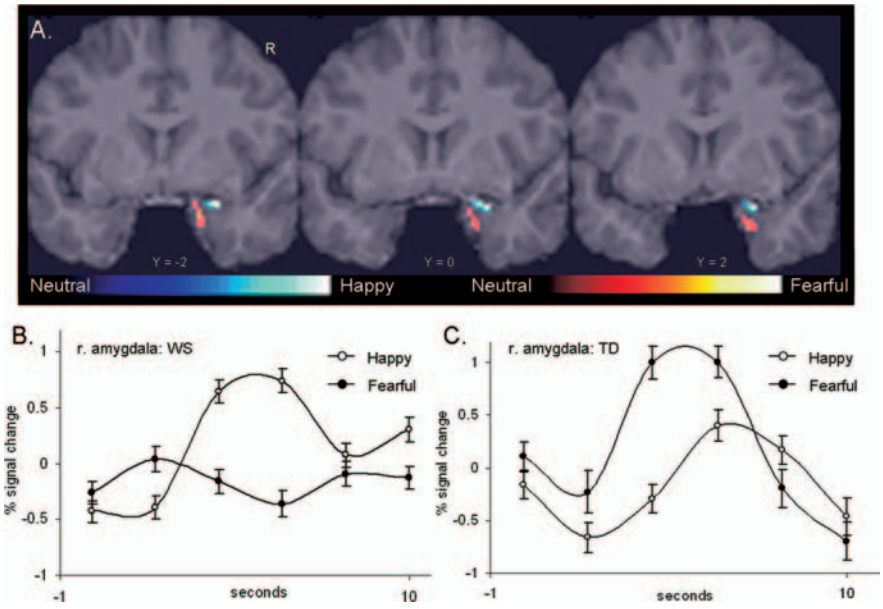

Figure 2. Areas of greater right amygdala reactivity to fearful and happy facial expressions (compared with neutral) within the WS and TD samples. ***A***, These clusters were not overlapping. We reduced the threshold to $p < 0.05$ uncorrected to visualize the distinct location for each cluster. No voxels within the right amygdala were found to be significantly activated in response to fear versus neutral in the WS group or happy versus neutral in the TD group at the same statistical threshold. Clusters are overlaid onto three coronal slices (Montreal Neurological Institute coordinates: $y = -2, 0, 2$) of a representative TD brain normalized into standard stereotactic space. Voxels of greater activation in response to happy versus neutral facial expressions in the WS group are designated by cool colors (blue). Voxels of greater activation in response to fearful versus neutral facial expressions in the TD group are designated by warm colors (orange). Extracted time course of percentage signal change for peak voxels within the clusters displayed in ***A*** are shown in ***B*** for WS participants and in ***C*** for TD participants. Data were extracted and converted to percentage signal change using a moving average (200 s) by a standardized method (xjview toolbox in SPM2). Lines denoted with open circles represent BOLD response to happy faces. Lines denoted with filled circles represent BOLD response to fearful faces. Error bars represent SEM. R, Right.

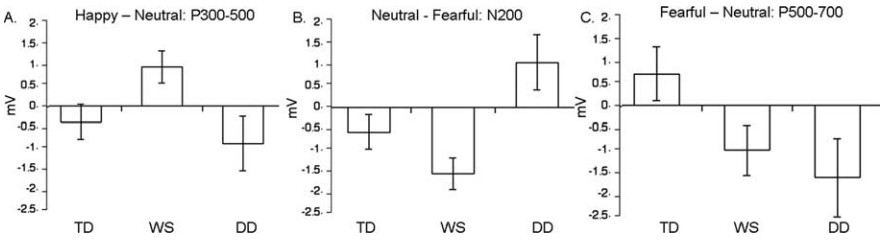

Figure 3. Direct comparison between groups for the P300–500 during happy relative to neutral facial expressions and the N200 and P500–700 during fearful relative to neutral facial expressions. ***A***, The P300–500 difference for happy − neutral was larger for WS than TD or DD groups. ***B***, For the N200, the WS group showed a larger N200 difference to neutral − fearful than TD or DD groups. ***C***, The P500–700 difference to fearful − neutral was larger for TD than WS or DD groups.

with neutral ($p < 0.05$ corrected; 12 voxels; MNI coordinates: 20, −6, −20) (Fig. 2*C*) and scrambled ($p < 0.05$ corrected; 39 voxels; MNI: 22, −4, −22) facial expressions. On the other hand, no significant left or right amygdala activation to fearful compared with neutral or scrambled facial expressions was observed in the WS group.

Amygdala response associated with IQ, reaction time, and accuracy

The fMRI study did not include a developmentally delayed control group as was available in the ERP study. Therefore, within the WS group, we examined the association of amygdala response with cognitive and behavioral variables that differentiated this group from TD controls. First, we entered IQ as a covariate with BOLD signal extracted from the right amygdala and found that there were no significant correlations between IQ and amygdala activity either in response to happy ($p = 0.57$) or fearful ($p = 0.48$) facial expressions within the WS group. Second, we entered reaction time and accuracy as covariates with BOLD signal extracted from the right amygdala and again found that there were no significant correlations between either reaction time or accuracy and activity either in response to happy or fearful facial expressions within the WS group (all p values >0.10).

ERPs

The organization of the ERP results section is designed to mirror the comparisons reported in the fMRI findings above. Thus, comparisons of ERP mean amplitudes linked to happy versus neutral expressions (P300–500) are followed by fearful versus neutral expressions (N200 and P500–700) respectively. In each section, we first report the overall emotion (happy or fearful vs neutral) × group (WS, TD, DD) interaction for a given ERP component. This is followed by tests of the predicted group differences for specific ERP emotion effects by using difference waves (e.g., P500 to happy minus neutral). These a priori hypotheses are further examined for each group individually. Finally, the specificity of the targeted emotion effects is examined for each ERP component. That is, where a significant emotion (happy or fearful vs neutral) × group (WS, TD, DD) interaction is observed, we conduct the same condition × group interaction analysis but substitute happy with fearful or fearful with happy. Throughout the ERP results section, p values that are <0.05 are referred to as significant, 0.05–0.10 as trends, and >0.10 as nonsignificant.

ERPs to happy facial expressions: P300–500

Based on visual inspection of the ERPs and previous research, ERPs to happy versus neutral expressions were examined from 300 to 500 ms (P300–500) for the WS, TD, and DD groups over six posterior sites (EGI locations, left: 29, 33, 42; right: 41, 34, 38) (Fig. 3*A*). The condition × group interaction indicated that the P300–500 response to happy versus neutral facial expressions was significantly different between the three groups ($F_{(2,66)} = 3.61$, $p = 0.03$, $\eta_p^2 = 0.100$) (Fig. 3*A*). We next tested the a priori hypothesis that the WS group would exhibit a greater P300–500 response to happy versus neutral facial expressions than the TD and DD control groups. Between-group comparisons showed that the P300–500 difference to happy minus neutral facial expressions was larger for the WS than for the TD group ($F_{(1,53)} = 7.189$, $p = 0.01$, $\eta_p^2 = 0.119$) or the DD group ($F_{(1,42)} = 5.362$, $p = 0.026$, $\eta_p^2 = 0.113$) but did not differ between the TD and DD groups ($F_{(1,37)} =$

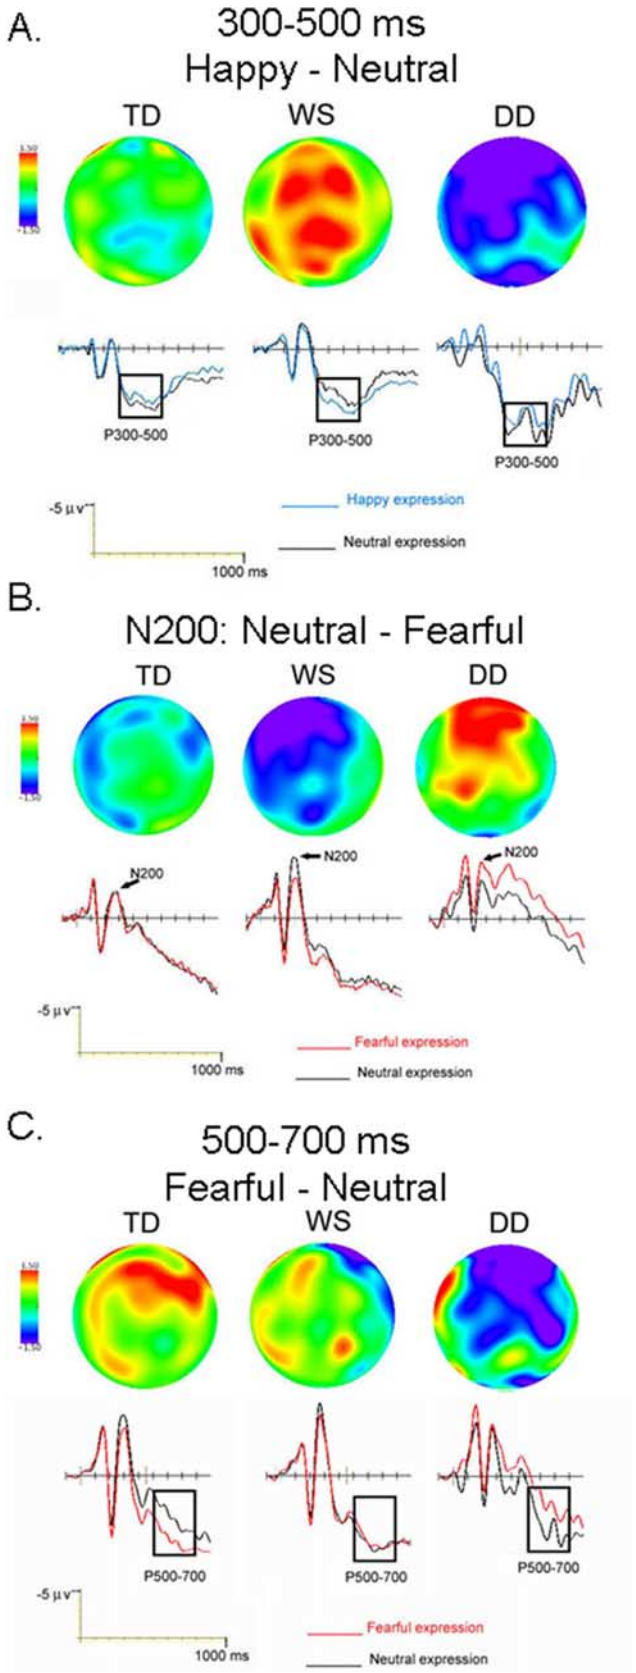

Figure 4. Event-related potentials and topographical maps comparing responses to different emotional expressions for the TD (left), WS (center), and DD (right) groups. Note that negative voltage is plotted up in all ERP plots. Topographical maps (top of each panel) illustrate the distribution of the difference in activity between conditions. Amplitude is plotted as a function of color with the most negative voltage as purple and most positive voltage as red. ***A***, ERPs to happy (blue lines) compared with neutral (black lines) expressions depicted at site 42 (P2). For the WS group, the P300–500 (boxed area) was larger to happy than neutral expressions. The P300–500 did not differ by emotional expression for the other two groups. The posterior central distribution of the happy − neutral difference wave at 350 ms is shown in the topographical map. ***B***, ERPs to neutral (black lines) compared with fearful (red lines) expressions shown at electrode 12 (AF3). The N200 amplitudes to fearful compared with neutral expressions are decreased in the WS group, and increased in the DD group. The topographical maps illustrate the anterior distribution of the N200 difference to fearful − neutral expressions at 240 ms. A larger N200 to fearful than neutral expression results in a positive difference that is represented in red as in the DD group (right side). In contrast, a smaller N200 to fearful than neutral expression results in a difference that is negative in voltage represented in purple as for the WS group. ***C***, ERPs to neutral (black lines) and fearful (red lines) expressions are shown at the bottom half of the figure shown at electrode 57 (next to FC4). The anterior positivity from 500 to 700 ms, P500–700 (boxed area), was larger to fearful than neutral expression for the TD controls (left) and did not differ for the WS group. For the DD group, the P500–700 appears to be larger to neutral than fearful expressions at this site, but the effect was not significant at this or other sites. The anterior distribution of the P500–700 difference wave to fearful − neutral expression at 520 ms is illustrated in the topographical maps.

0.621, $p = 0.436$). We next compared P300–500 response to happy versus neutral facial expressions in the WS, TD, and DD groups independently (Fig. 4*A*). The WS group exhibited a greater P300–500 response to happy versus neutral facial expressions ($F_{(1,29)} = 4.502$, $p = 0.043$, $\eta_p^2 = 0.136$). In contrast, the P300–500 response to happy versus neutral facial expressions was not different for the TD ($F_{(1,24)} = 0.892$, $p = 0.354$) or DD ($F_{(1,14)} = 1.817$, $p = 0.201$) groups.

We examined the specificity of emotion by comparing fearful versus neutral P300–500 response over posterior regions between the three (WS, TD, and DD) experimental groups (condition × group interaction). The condition × group interaction indicated that the P300–500 response to fearful versus neutral facial expressions was not significantly different between the three groups ($F_{(2,66)} = 1.426$, $p = 0.248$), nor was the P300–500 comparison to fearful versus neutral expressions significant for any individual group: TD, $F_{(1,24)} = 0.046$, $p = 0.832$; WS, $F_{(1,29)} = 0.374$, $p = 0.546$; DD, $F_{(1,14)} = 1.435$, $p = 0.252$.

Event-related responses to fearful facial expressions: N200 and P500–700

N200

We compared the N200 mean amplitude and peak latency to fearful versus neutral expressions for the three groups (WS, TD, and DD) over the left and right hemisphere (total of 16 sites) (see supplemental Fig. 1, available at www.jneurosci.org as supplemental material). The condition × group interaction indicated that the N200 to fearful versus neutral facial expressions was significantly different between groups in mean amplitude ($F_{(2,66)} = 4.531$, $p = 0.014$, $\eta_p^2 = 0.122$), group × emotion × electrode site ($F_{(2,66)} = 2.363$, $p = 0.034$, $\eta_p^2 = 0.067$) (Fig. 3*B*). There were no condition × group effects for peak latency ($F_{(2,66)} = 0.290$, $p = 0.749$). We next tested the a priori hypothesis that the WS group would exhibit decreased neural activity to fearful versus neutral facial expressions relative to the TD and DD control groups. Between-group comparisons showed that the N200 difference wave to fearful minus neutral facial expressions tended to be greater (more negative) for the WS than for the TD group over the left hemisphere ($F_{(1,53)} = 3.321$, $p = 0.07$) and was greater (more negative) for WS than for the DD group ($F_{(1,42)} = 8.327$, $p = 0.006$, $\eta_p^2 = 0.165$). In contrast, the effect was smaller (more positive) for the DD than for the TD group ($F_{(1,37)} = 4822$, $p = 0.034$, $\eta_p^2 = 0.115$). We next compared the N200 to fearful versus neutral facial expressions in the WS, TD, and DD groups inde-

pendently (Fig. 4*B*). For the WS group, the N200 was smaller to fearful than neutral expressions over the left hemisphere, condition × hemisphere ($F_{(1,29)} = 13.048$, $p = 0.001$, $\eta_\rho^2 = 0.316$), and peaked significantly earlier ($F_{(1,29)} = 14.350$, $p = 0.001$). In contrast, for the TD group, the N200 did not differ in mean amplitude to fearful versus neutral expressions ($F_{(1,24)} = 1.253$, $p = 0.214$) or peak latency ($F_{(1,23)} = 1.997$, $p = 0.171$). Although the DD group did not show N200 mean amplitude ($F_{(1,14)} = 2.089$, $p = 0.172$) or latency ($F_{(1,14)} = 0.724$, $p = 0.495$) differences over these electrodes, they did show increased N200 amplitudes to fearful relative to neutral expressions over different central (more medial) regions (13, 4, 62; F5, F3, F4) ($F_{(1,14)} = 4.847$, $p = 0.046$, $\eta_\rho^2 = 0.272$).

We examined the specificity of the N200 responsiveness to fearful versus neutral emotions by comparing the N200 amplitude to happy versus neutral expressions over the same 16 regions for the three (WS, TD, and DD) experimental groups (condition × group interaction). The N200 response to happy versus neutral facial expressions was not significantly different between the three groups ($F_{(2,66)} = 2.185$, $p = 0.121$).

P500–700

We compared the P500–700 mean amplitude to fearful versus neutral expressions for the three groups at 14 sites (EGI sites, left: 14, 12, 19, 15, 13, 20, 16; right: 1, 2, 60, 61, 62, 56, 57) (Fig. 3*C*; supplemental Fig. 1, available at www.jneurosci.org as supplemental material). The predicted emotion × group × hemisphere interaction only approached significance ($F_{(2,66)} = 2.838$, $p = 0.066$). Based on the current fMRI findings showing increased right amygdala activation to fearful relative to neutral stimuli in the TD group, and previous ERP research showing an increased positivity over right anterior regions in the 500–700 ms range linked to fearful relative to neutral expressions, we predicted that the TD group would show an increased positivity, whereas the WS group would show a diminished positivity, to fearful relative to neutral expressions. Therefore, we tested the a priori hypothesis that the WS group would exhibit decreased response to fearful versus neutral facial expressions relative to the TD and DD control groups. Between-group comparisons showed that the P500–700 difference to fearful minus neutral facial expressions was larger for the TD group than for the WS groups over right anterior regions ($F_{(1,53)} = 4.337$, $p = 0.042$, $\eta_\rho^2 = 0.076$). The P500–700 difference to fearful minus neutral facial expressions did not significantly differ between the WS and the DD groups ($F_{(1,42)} = 1.717$, $p = 0.197$) at any electrode site. However, there was a trend for the P500–700 difference to fearful minus neutral facial expressions to be different between the TD and DD groups ($F_{(1,37)} = 3.329$, $p = 0.08$). We next compared P500–700 response to fearful versus neutral facial expressions in the WS, TD, and DD groups independently (Fig. 4*C*). For the WS group, the P500–700 response to fearful versus neutral facial expressions was smaller over the right hemisphere ($F_{(1,29)} = 6.376$, $p = 0.017$, $\eta_\rho^2 = 0.180$). For the TD group, the P500–700 response to fearful versus neutral facial expressions tended to be larger over right anterior regions [$F_{(1,24)} = 3.335$, $p = 0.08$, $\eta_\rho^2 = 0.115$; at electrode 57 (FC6), $t_{(24)} = 2.342$, $p = 0.028$]. For the DD group, the P500–700 response to fearful versus neutral facial expressions was not significantly different at any site ($F_{(1,14)} = 1.345$, $p = 0.267$).

We examined the specificity of emotion by comparing happy versus neutral P500–700 response over the same regions between the three (WS, TD, and DD) experimental groups. The emotion × group interactions indicated that the P500–700 response to happy versus neutral facial expressions was not significantly different between the three groups ($F_{(2,66)} = 1.081$, $p = 0.345$; group × emotion × hemisphere, $F_{(2,66)} = 0.152$, $p = 0.860$).

Discussion

Results from the fMRI and ERP studies using identical stimuli and a similar experimental design provided convergent evidence that individuals with WS exhibit both heightened amygdala reactivity to happy facial expressions and diminished amygdala reactivity to fearful facial expressions. The heightened amygdala response to socially appetitive stimuli may be a fundamental neural substrate that underlies atypical social drive in WS. Similar to the results of a previous study (Meyer-Lindenberg et al., 2005), we also found that TD healthy controls exhibited a robust amygdala response to fearful facial expressions, while the WS group did not, although the condition × group interaction (using neutral as a baseline) approached corrected statistical significance. By using an additional methodological approach (ERPs), we were able to provide an electrophysiological correlate of these fMRI findings and to examine the temporal specificity of the neural response to fearful stimuli within each group. Specifically, the WS group showed decreased activity to fearful versus neutral expressions as reflected by decreases in the mean amplitudes of the N200, compared with both the DD and TD groups. The significant between-group differences in N200 amplitude provide evidence that relatively early during the visual and perceptual stream, WS individuals differ from both healthy and IQ-matched controls in how fearful facial expressions are processed.

Of particular interest here was that the WS group showed increased activity to happy relative to neutral expressions as evidenced by relative increases in BOLD signals in the right amygdala and amplitude of the posterior P300–500 waveform. The posterior P300–500 ERP effect has been linked to enhanced memory for emotional content and may reflect increased attention to emotionally salient stimuli during encoding (Deidrich et al., 1997; Dolcos and Cabeza, 2002; Koenig and Mecklinger, 2008). Regarding the ERPs to fearful faces, we did not predict that the P500–700 difference to fearful minus neutral facial expressions would be different between the TD and DD groups. An ERP/fMRI study of positive, negative, and emotional scenes showed that the amplitude of the late posterior positivity indexes emotional intensity (Sabatinelli et al., 2007) and is correlated with activation from the amygdala (Sabatinelli et al., 2005). The present data represent a new finding and are the first to show increased neural activity to positive emotional expressions in WS.

Considering the fMRI findings for both positively and negatively valenced social stimuli, the clusters of fMRI activation within the right amygdala were observed to be nonoverlapping (Fig. 2*A*). This suggests that distinct neuronal populations may subserve these functions and that this effect may be primarily lateralized to the right amygdala. Recently, single-unit recording studies in primates have indicated the presence of emotion selective neurons within the amygdala (Paton et al., 2006; Kuraoka and Nakamura, 2007). Although some lesion studies in rats indicate that disparate nuclei within the amygdala are engaged in different functions (Knapska et al., 2007; Yang et al., 2008), other studies suggest that amygdala nuclei function in parallel during appetitive and aversive processing (Balleine and Killcross, 2006). The fact that the results in this study are based on averaged, spatially smoothed data limits how precisely the clusters can be assigned to specific nuclei within the amygdala. However, a single-subject analysis based on nonsmoothed data confirms the general topographical dissociation of amygdala activation be-

tween groups but also demonstrates the heterogeneity of BOLD signal within groups (supplemental Fig. 2, available at www.jneurosci.org as supplemental material). The putative dissociation of these loci suggests that the genetic deletion in WS may influence the development and function of separate amygdala regions (and possibly nuclei) differently.

The increased amygdala response to happy facial expressions in individuals with WS may represent several psychological processes linked to the amygdala including attention, arousal, or anxiety. For example, the central nucleus of the amygdala has been strongly linked with attention (Holland and Gallagher, 1999; Maddux et al., 2007). Although eye-tracking information would have helped clarify this issue in our study, unfortunately, equipment to obtain these data were not available at the time of subject scanning. However, other investigations have assessed attentional mechanisms during social processing in WS by measuring gaze duration of infants and toddlers toward faces (Mervis et al., 2003), or by performing eye tracking when subjects viewed social and nonsocial stimuli (Riby and Hancock, 2008). The results of these studies indicate that WS is associated with enhanced attention for social and emotional stimuli. For example, whereas individuals with autism tend to exhibit reduced fixation toward faces and eyes, people with WS exhibit heightened amounts of fixation toward faces and eyes (Riby and Hancock, 2008) relative to typically developing and nonverbal ability-matched controls. Although demonstrating a WS-associated predisposition for increased attention to social–emotional stimuli in general, these studies did not directly address differential attention for or neural responses to positive versus negative emotional stimuli in affected individuals.

The social phenotype in WS has been described as being comprised of relative strengths and weaknesses (Mervis, 2003; Feinstein and Singh, 2007). On one hand, those with WS appear to be particularly driven toward engaging in social interaction and to approach others such as strangers excessively and inappropriately. Neuropsychological research has demonstrated that individuals with WS tend to rate happy facial expressions as more approachable relative to other emotions than do mentally aged controls (Frigerio et al., 2006; Porter et al., 2007). On the other hand, those with WS often experience profound difficulties maintaining relationships and also experience heightened levels of anxiety during social interaction (Dykens, 2003). The data from the current study is consistent with this behavioral phenotype of WS and provides neurobiological evidence that the WS social phenotype is mediated by both increased neural reactivity to happy expressions and decreased reactivity to fearful expressions. The heightened amygdala activity during the processing of happy facial expressions in WS may be a neural marker of anticipatory processes that precede events during which the likelihood of social engagement is high.

Our current study is limited by several constraints defined by our subject groups and experimental design. WS is often associated with general delays in cognitive development. In our ERP study, we took advantage of an IQ-matched (developmentally delayed) control group to demonstrate that the observed responsiveness to social stimuli was not driven by IQ. Due to limited recruitment that yielded poor statistical power, we were not able to use such a control group for our fMRI study. However, we undertook several procedures to investigate whether the observed differences between the WS and TD group in the fMRI study were driven by differences in either IQ or behavioral responses. The findings from these analyses, as well as from the ERP study that included DD controls, indicate that differences in IQ or task performance are not driving the significant between-group fMRI findings in amygdala response to positive and negative social stimuli.

Our data provide evidence that a fundamental characteristic of the WS phenotype consists of aberrant neural reactivity to emotional facial expressions. It is unclear, however, what specific components of facial expressions may correspond with this differential response. Previous studies have reported impaired (Gagliardi et al., 2003; Plesa-Skwerer et al., 2006), as well as preserved (Santos et al., 2008), functioning in face recognition in WS. Additionally, in terms of social cognition, it has been speculated that those with WS exhibit a relatively preserved ability to empathize with others (Mervis and Klein-Tasman, 2000) and that they tend to be relatively socially anxious (Dykens, 2003). Future developments in neuropsychological assessment techniques may strengthen our understanding of the relationship between these psychological constructs and the differences in neural activation reported here.

Advancements in social cognitive neuroscience have demonstrated that brain responses to emotional stimuli vary according to task instructions and states, such as mood (Haas and Canli, 2008). In a previous study, Meyer-Lindenberg et al. (2005) provided evidence of atypical amygdala function during social processing by using a matching task (faces vs shapes). Our study used similar negative (fearful) social stimuli but also included positive (happy) social stimuli and a different set of task instructions (gender discrimination). The convergence between the patterns of results between the two types of tasks strengthens the hypothesis that amygdala abnormality is a primary neural substrate that underlies the social phenotype in WS. Continued research that uses different task instructions and assesses other between-subject characteristics, such as mood and personality, will further advance the existing model of WS and social cognitive brain function.

In summary, this article provides new fMRI and ERP evidence that persons with WS exhibit heightened amygdala and cortical response to happy facial expressions and extends previous research that demonstrated absent or reduced response to fear in WS. This finding provides a neural correlate to previous behavioral findings reporting the tendency to be overly socially appetitive in WS. Future studies will extend our understanding of the genetic influences of social behavior in WS and the interaction between the amygdala and other brain regions associated with social cognition.

Genetics of Mouse Behavior: Interactions with Laboratory Environment

John C. Crabbe,[1]* Douglas Wahlsten,[2] Bruce C. Dudek[3]

Strains of mice that show characteristic patterns of behavior are critical for research in neurobehavioral genetics. Possible confounding influences of the laboratory environment were studied in several inbred strains and one null mutant by simultaneous testing in three laboratories on a battery of six behaviors. Apparatus, test protocols, and many environmental variables were rigorously equated. Strains differed markedly in all behaviors, and despite standardization, there were systematic differences in behavior across labs. For some tests, the magnitude of genetic differences depended upon the specific testing lab. Thus, experiments characterizing mutants may yield results that are idiosyncratic to a particular laboratory.

Targeted and chemically induced mutations in mice are valuable tools in biomedical research, especially in the neurosciences and psychopharmacology. Phenotypic effects of a knockout often depend on the genetic background of the mouse strain carrying the mutation (*1*), but the effects of environmental background are not generally known.

Different laboratories commonly employ their own idiosyncratic versions of behavioral test apparatus and protocols, and any laboratory environment also has many unique features. These variations have sometimes led to discrepancies in the outcomes reported by different labs testing the same genotypes for ostensibly the same behaviors (*2*). Previous studies could not distinguish between interactions arising from variations in the test situation itself and those arising from subtle environmental differences among labs. Usually, such differences are eventually resolved by repetition of tests in multiple labs. However, null mutants and transgenic mice are often scarce and tend to be behaviorally characterized in a single laboratory with a limited array of available tests.

We addressed this problem by testing six mouse behaviors simultaneously in three laboratories (Albany, New York; Edmonton, Alberta, Canada; and Portland, Oregon) using exactly the same inbred strains and one null mutant strain (*3*). We went to extraordinary lengths to equate test apparatus, testing protocols, and all possible features of animal husbandry (*4*). One potentially important feature was varied systematically. Because many believe that mice tested after shipping from a supplier behave differently from those reared in-house, we compared mice either shipped or bred locally at the same age (77 days) starting at the same time (0830 to 0900 hours local time on 20 April 1998) in all three labs (*5*). Each mouse was given the same order of tests [Day 1: locomotor activity in an open field; Day 2: an anxiety test, exploration of two enclosed and two open arms of an elevated plus maze; Day 3: walking and balancing on a rotating rod; Day 4: learning to swim to a visible platform; Day 5: locomotor activation after cocaine injection; Days 6 to 11: preference for drinking ethanol versus tap water (*6*)].

Despite our efforts to equate laboratory environments, significant and, in some cases, large effects of site were found for nearly all variables (Table 1). Furthermore, the pattern of strain differences varied substantially among the sites for several tests. Sex differ-

Table 1. Statistical significance and effect sizes for selected variables in the multisite trial. Color of cell depicts Type I error probability or significance of main effects and two-way interactions from 8 × 2 × 3 × 2 analyses of variance: blue, $P < 0.00001$; purple, $P < 0.001$; gold, $P < 0.01$; dashes with no shading, $P > 0.01$. Cell entries are effect sizes, expressed as partial omega squared, the proportion of variance accounted for by the factor or interaction if only that factor were in the experimental design (range = 0 to 1.0). Multiple R^2 (unbiased estimate) gives the proportion of the variance accounted for by all factors. For the water escape task, results are based on only seven strains because most A/J mice never escaped because of wall-hugging. We recognize that the issue of appropriate alpha level correction for multiple comparisons is contentious. Details of the statistical analyses are available on the Web site (*4*), including a discussion of our rationale for presenting uncorrected values in this table.

Task	Measure	Eight Genotypes	Three Sites	Two Sexes	Local vs Shipped	Genotype x Site	Genotype x Sex	Genotype x Ship	Multiple R^2
Open field	Distance in 15 min	.600	.157	----	----	.059	.045	----	.604
Open field	# vertical movements	.788	.281	.039	----	----	----	----	.772
Cocaine	Difference from Day 1	.338	.053	----	----	.086	----	----	.342
Plus maze	Total arm entries	.385	.327	----	----	.210	----	----	.660
Plus maze	Time in open arms	.082	.212	----	----	.066	----	----	.266
Water maze	Mean escape latency	.221	----	----	.026	----	----	----	.177
Alcohol preference	Alcohol consumed (g/kg)	.483	----	.043	----	----	----	----	.451
Body size	Weight (g)	.408	.204	.637	----	.071	.070	----	.698

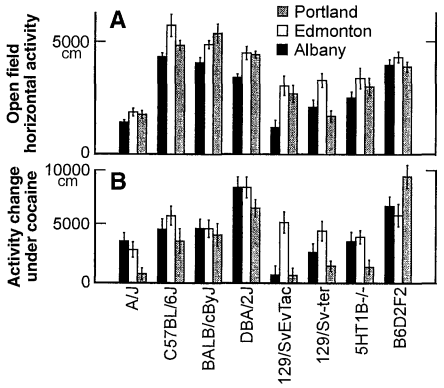

Fig. 1. Group means (±SEM for $n = 16$ mice) for activity in a 40 cm by 40 cm open field for eight strains tested at the same time of day in identical apparatus in three laboratories. (**A**) Horizontal distance (centimeters) traveled in 15 min on the first test on Day 1. (**B**) Cocaine-induced activation, expressed as the difference between horizontal activity (centimeters in 15 min) after cocaine (20 mg/kg) on Day 5 minus the score on Day 1.

ences were only occasionally detected, and, much to our surprise, there were almost no effects of shipping animals before testing. Large genetic effects on all behaviors were confirmed, which is not surprising because we chose strains known to differ markedly on these tasks.

Results for locomotor activity and the effect of a subsequent cocaine injection on locomotion are shown in Fig. 1. Expected strain differences in undrugged activity were found: A/J mice were relatively inactive at all three sites, whereas C57BL/6J mice were very active. An effect of laboratory was also found: mice tested in Edmonton were, on average, more active than those tested in Albany or Portland. In addition, the pattern of genetic differences depended on site. For example, 129/SvEvTac mice tested in Albany were very inactive compared to their counterparts in other labs. Similar results were seen for sensitivity to cocaine stimulation. For example, B6D2F2 mice were very responsive (and A/J mice quite insensitive) to cocaine in Portland, but not at other sites.

In the elevated plus maze, a very similar pattern was seen: strong effects of genotype, site, and their interaction. This was true both for activity measures and for time spent in open arms, the putative index of anxiety (Fig. 2). For total arm entries, the testing laboratory was particularly important for the 5-HT_{1B} knockout mice versus their wild-type 129/Sv-ter background controls. Knockout mice had greater activity than wild types in Portland and tended to have less activity in Albany, while not differing in Edmonton. Edmonton mice of all strains spent more time in open arms (lower anxiety). Portland mice also spent less time in open arms, but this was especially true for strains A/J, BALB/cByJ, and the B6D2F2 mice.

Although the testing laboratory was an important variable, there was a good deal of consistency to the genetic results as well. For example, comparison of the genotype means (averaged over sites) for the initial 5 min of the activity test on Day 1 with the total arm entry scores from the plus maze yielded a high correlation between strains ($r = 0.91$, $P < 0.002$). This indicates that a strain's characteristic activity in novel apparatus is robust and occurs in different apparatus as well as different labs (*7*).

For some behaviors, laboratory environment was not critical. For example, ethanol drinking scores were closely comparable across all three labs, and genotypes alone accounted for 48% of the variance (Table 1 and Fig. 3). The genetic differences showed the well-known pattern of C57BL/6J mice strongly preferring and DBA/2J mice avoiding ethanol (*8*). Females drank more, as is also well known (*8*), but there were no significant effects of site, shipping, or any other interactions. Unlike the other five tests, ethanol preference testing extended over 6 days in the home cage and involved a bare minimum of handling mice by the experimenter.

For some measures, the difference between 5-HT_{1B} null mutant and wild-type mice depended on the specific laboratory environment. In Edmonton, for example, no difference was observed between +/+ and –/– mice in distance traveled in the activity monitor, whereas there was greater activity in the knockouts at the other two sites, especially Portland ($P = 0.002$). In the elevated plus maze, knockouts were considerably more active than wild types only in Portland (Fig. 2A; $P = 0.02$).

The numbers of mice we tested made formal statistical assessment of reliability infeasible, but it would be important to know whether each laboratory would obtain essentially the same strain-specific results if this experiment were repeated. Because our experiment included an internal replication, we estimated the lower bounds of reliability for each site separately by correlating the mean scores for each strain (collapsed over sex and shipping group) obtained during the two replicates of the experiment. These correlations differed depending upon the behavior, and were consonant with the relative importance of genotype in the overall analysis. For example, for locomotor activity, the correlations were 0.97, 0.74, and 0.87 for the three sites. For open-arm time on the plus maze, possibly the most intrinsically unstable task we employed, the correlations were lower (0.32, 0.52, and 0.26). These can be compared to correlations for body weight, which can serve as a type of control variable not influenced by idiosyncratic dynamics of the test situation (0.83, 0.74, and 0.90). No site had generally higher or lower reliability than the others, and formal analyses of replication in analyses of variance indicated no strong interactions of strain by replication. We conclude that reasonable estimates of strain-specific scores are highly dependent on behavioral endpoint, and that some behaviors are highly stable.

Several sources of these laboratory-specific behavioral differences could be ruled out by the rigor of the experimental design. For example, Edmonton mice might have been

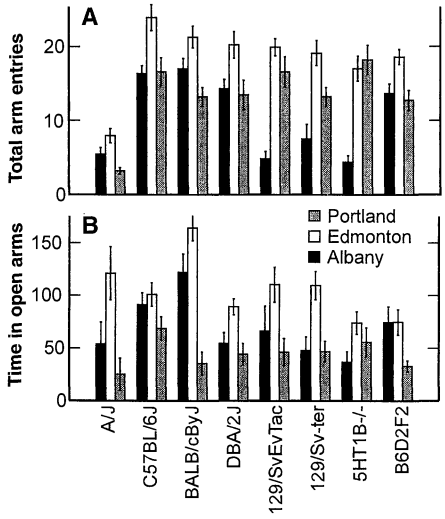

Fig. 2. Group means (±SEM for $n = 16$ mice) for behavior videotaped for 5 min on elevated plus mazes having two open and two enclosed arms. (**A**) Total number of entries into any arm (defined as all four limbs in the arm). (**B**) Time (seconds) spent in the two open arms during the 300-s test. Smaller amounts of time indicate higher levels of anxiety.

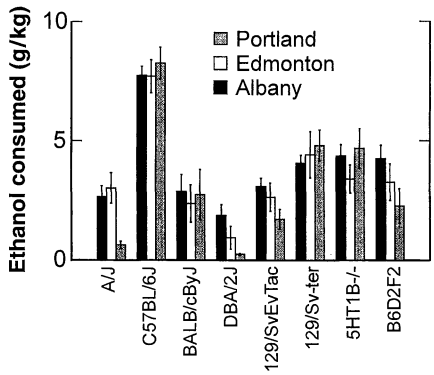

Fig. 3. Mean (±SEM) ethanol consumed per day, expressed as grams per kilogram body weight, over 4 days of an ethanol preference test where each mouse had free access to two drinking bottles, one with local tap water and the other with 6% ethanol in tap water.

more sensitive to cocaine-induced locomotion because the source of cocaine differed from the other two sites (*4*), but this could not explain the relatively marked response of the three 129-derived strains in Edmonton only. However, specific experimenters performing the testing were unique to each laboratory and could have influenced behavior of the mice. The experimenter in Edmonton, for example, was highly allergic to mice and performed all tests while wearing a respirator—a laboratory-specific (and uncontrolled) variable.

Whether animals were bred in each laboratory or shipped as adults 5 weeks before testing had no consistent influence on results in this experiment. Shipped animals took routes of varying duration and difficulty. For example, some Taconic mice were trucked to Albany from nearby Germantown, New York, whereas others spent 2 days in transit during a flight in midwinter to Edmonton. At least in this experiment, allowing animals a lengthy period of acclimation to new quarters was sufficient to overcome any strong effects of putative shipping stress on subsequent behavior.

These results support both optimistic and pessimistic interpretations. Seen optimistically, genotype was highly significant for all behaviors studied, accounting for 30 to 80% of the total variability, and several historically documented strain differences were also seen here. In general, we conclude that very large strain differences are robust and are unlikely to be influenced in a major way by site-specific interactions. However, a more cautious reading suggests that for behaviors with smaller genetic effects (such as those likely to characterize most effects of a gene knockout), there can be important influences of environmental conditions specific to individual laboratories, and specific behavioral effects should not be uncritically attributed to genetic manipulations such as targeted gene deletions.

When studying mutant mice, relatively small genetic effects should first be replicated locally before drawing conclusions (*9*). We further recommend that, if possible, genotypes should be tested in multiple labs and evaluated with multiple tests of a single behavioral domain (such as several tests of anxiety-related behavior) before concluding that a specific gene influences a specific behavioral domain. We also suggest the possibility that laboratory-specific effects on genetic differences will affect phenotypes other than behaviors to an extent similar to that we report.

It is not clear whether standardization of behavioral assays would markedly improve future replicability of results across laboratories. Standardization will be difficult to achieve because most behaviorists seem to have differing opinions about the "best" way to assay a behavioral domain. For example, two of us typically test behavior during the light phase of the animals' cycle, whereas the third typically tests during the dark phase (but switched to the light phase for this study). Which apparatus specifications or test protocol to employ is also a subject of differing opinion. There is a risk of prematurely limiting the "recommended" tests in a domain to those deemed "industry standard," because this may constrain the intrinsic richness of a domain and obscure interesting interactions. On the other hand, increased communication and collaboration between the molecular biologists creating mutations and behavioral scientists interested in the psychological aspects of behavioral testing will benefit both groups.

2. It has been known for some time that comparisons of multiple genotypes on learning-related tests do not always yield consistent results across laboratories [D. Wahlsten, in *Psychopharmacology of Aversively Motivated Behavior*, H. Anisman and G. Bignami, Eds. (Plenum, New York, 1978), pp. 63–118]. For another example, the Crabbe laboratory has reported that C57BL/6 mice show a small enhancement of locomotor activity after low doses of ethanol, while the Dudek laboratory finds no such stimulant response [J. C. Crabbe *et al.*, *J. Comp. Physiol. Psychol.* **96**, 440 (1982); B. C. Dudek and T. J. Phillips, *Psychopharmacology* **101**, 93 (1990)]. Similar variation has been reported in other measures of activity in various laboratories and apparatus [J. M. LaSalle and D. Wahlsten, in *Techniques for the Genetic Analysis of Brain and Behavior: Focus on the Mouse*, D. Goldowitz, D. Wahlsten, R. E. Wimer, Eds. (Elsevier, Amsterdam, 1992), pp. 391–406].
3. We tested males and females from the inbred strains: A/J, BALB/cByJ, C57BL/6J, DBA/2J, 129/Sv-ter, and 129/SvEvTac; the F_2 hybrid cross of C57BL/6J and DBA/2J (B6D2F2); and the serotonin receptor subtype null mutant, 5-$HT_{1B}^{-/-}$, which is maintained on the 129/Sv-ter background. Mice were obtained from the Jackson Laboratory (Bar Harbor, ME), Taconic Farms (Germantown, NY), or the colonies of R. Hen (Columbia University, New York, NY). Because many targeted deletions are placed on the 129/SvEvTac background, we included this close relative of 129/Sv-ter. The genealogy of many 129 substrains has recently been discussed [E. M. Simpson *et al.*, *Nature Genet.* **16**, 19 (1997); D. W. Threadgill, D. Yee, A. Matin, J. H. Nadeau, T. Magnuson, *Mamm. Genome* **8**, 390 (1997)].
4. Details of procedures and test protocols are given in the Web site for this study (www.albany.edu/psy/obssr). Variables explicitly equated across laboratories included apparatus, exact testing protocols, age of shipped and laboratory-reared mice, method and time of marking before testing, food (Purina 5001; Purina 5000 for breeders), bedding (Bed-o-cob, 1/4 inch; Animal Specialties, Inc., Hubbard, OR), stainless steel cage tops, four to five mice per cage, light/dark cycle, cage changing frequency and specific days, male left in cage after births, culling only of obvious runts, postpartum pregnancy allowed, weaned at 21 days, specific days of body weight recording, and gloved handling without use of forceps. Unmatched variables included local tap water, requirement of filters over cage tops in Portland only, variation of physical arrangement of colonies and testing rooms across sites, different air handling and humidity, and different sources of batches of cocaine and alcohol.
5. All breeding stock was shipped on 2 or 3 December 1997, and mating pairs were set simultaneously on 13 January 1998 in all labs to provide "unshipped" mice for testing. On 15 to 17 March 1998, a second batch of mice from each genotype was shipped to each laboratory. These "shipped" mice, age matched with the unshipped cohort already in place, were allowed to acclimate to the laboratory for 5 weeks before testing commenced. We tested 128 mice in each lab, in two groups of 64 separated by 1 week. With an $n = 4$ mice in each genotype/shipping condition/sex/laboratory condition, we had 16 mice per group for the crucial genotype × laboratory comparisons. This sample size gave us statistical power of 90% to detect modest interactions of genotype × laboratory when Type I error probability was set at 0.01 [J. Cohen, *Statistical Power Analysis* (Erlbaum, Hillsdale, NJ, 1988); D. Wahlsten, *Behav. Brain. Sci.* **13**, 109 (1990)]. For results of analysis of variance, we report only effects significant at $P < 0.01$. The Web site in (*4*) provides detailed protocols used for each test, descriptions of the laboratory conditions rigorously equated across labs, and raw data that may be examined for other interesting patterns.
6. AccuScan Digiscan monitors (AccuScan Instruments, Columbus, OH) were generously loaned to D. Wahlsten by R. H. Kant to match those available in the other two laboratories. AccuScan also provided all sites with rotarod apparatus. Mouse-scaled water mazes and elevated plus mazes were constructed by D. Wahlsten and shipped to the other two labs. On the first test day, each mouse was tested for 15 min in a Digiscan open-field monitor in a dark, sound-attenuated chamber. On Day 2, each mouse was videotaped for 5 min in an elevated plus maze. On Day 3, mice were given 10 trials on a rotarod set to accelerate from 0 to 100 rpm in 75 s. After all mice had been tested on the rotarod, mice were pretrained briefly to escape from the water maze. On Day 4, mice were given eight massed trials of escape learning to a visible platform in the water maze. On Day 5, the activity test was repeated immediately following an ip injection of 20 mg of cocaine per kilogram. After 2 days of rest, mice were individually housed, given only tap water for 2 days, and then tested for 4 days for drinking of 6% ethanol in tap water versus tap water alone.

8. G. E. McClearn and D. A. Rodgers, *Q. J. Stud. Alcohol* **20**, 691 (1959); J. K. Belknap, J. C. Crabbe, E. R. Young, *Psychopharmacology* **112**, 503 (1993); L. A. Rodriguez *et al.*, *Alcohol. Clin. Exp. Res.* **19**, 367 (1995).
9. It was previously reported that 5-HT_{1B} null mutant mice drank much more alcohol than the 129/Sv-ter wild-type strain [J. C. Crabbe *et al.*, *Nature Genet.* **14**, 98 (1996)]. In the experiments here, no site detected this difference (Fig. 3 and Table 1). The original outcome was replicated four times (J. C. Crabbe *et al.*, unpublished data). It is possible that residual polymorphisms for genes segregating in the 129/SvPas substrain that served as the original source of the embryonic stem cell line and in the 129/Sv-ter substrain to which the null mutant was crossed have subsequently been fixed differentially in the 5-HT_{1B} +/+ and –/– strains maintained at Columbia University (*3*). If so, these genes must exert very large epistatic effects on the 1B gene deletion's phenotypic effects on drinking (*1*). Alternatively, some undetected variable (for example, a change in animal care personnel) may have occurred specifically at the Portland site between the original (1995–96) observations and the current experiments.

Genome-wide association analyses identify 44 risk variants and refine the genetic architecture of major depression

Major depressive disorder (MDD) is a common illness accompanied by considerable morbidity, mortality, costs, and heightened risk of suicide. We conducted a genome-wide association meta-analysis based in 135,458 cases and 344,901 controls and identified 44 independent and significant loci. The genetic findings were associated with clinical features of major depression and implicated brain regions exhibiting anatomical differences in cases. Targets of antidepressant medications and genes involved in gene splicing were enriched for smaller association signal. We found important relationships of genetic risk for major depression with educational attainment, body mass, and schizophrenia: lower educational attainment and higher body mass were putatively causal, whereas major depression and schizophrenia reflected a partly shared biological etiology. All humans carry lesser or greater numbers of genetic risk factors for major depression. These findings help refine the basis of major depression and imply that a continuous measure of risk underlies the clinical phenotype.

MDD is a notably complex and common illness[1]. It is often chronic or recurrent and is thus accompanied by considerable morbidity, disability, excess mortality, substantial costs, and heightened risk of suicide[2–8]. Twin studies attribute approximately 40% of the variation in liability to MDD to additive genetic effects (phenotype heritability, h^2)[9], and h^2 may be greater for recurrent, early-onset, and postpartum MDD[10,11]. Genome-wide association studies (GWAS) of MDD have had notable difficulties in identifying individual associated loci[12]. For example, there were no significant findings in the initial Psychiatric Genomics Consortium (PGC) MDD mega-analysis (9,240 cases)[13] or in the CHARGE meta-analysis of depressive symptoms ($n = 34{,}549$)[14]. More recent studies have proven modestly successful. A study of Han Chinese women (5,303 recurrent MDD cases) identified significant loci[15], a meta-analysis of depressive symptoms (161,460 individuals) identified 2 loci[16], and an analysis of self-reported major depression identified 15 loci (75,607 cases).

There are many reasons why identifying causal loci for MDD has proven difficult[12]. MDD is probably influenced by many genetic loci, each with small effects[17], as are most common diseases[18], including psychiatric disorders[19,20]. Estimates of the proportion of variance attributable to genome-wide SNPs (SNP heritability, h^2_{SNP}) indicate that around one-quarter of the h^2 for MDD is due to common genetic variants[21,22] and demonstrate that a genetic signal is detectable in genome-wide association data, implying that larger sample sizes are needed to detect specific loci given their effect sizes. Such a strategy has been proven in studies of schizophrenia, the flagship adult psychiatric disorder in genomics research. We thus accumulated clinical, population, and volunteer cohorts[23]. This pragmatic approach takes the view that sample size can overcome heterogeneity to identify risk alleles that are robustly associated with major depression. Potential concerns about combining carefully curated research cohorts with volunteer cohorts were considered; multiple lines of evidence suggest that the results are likely to be applicable to clinical MDD. As discussed below, our analyses have neurobiological, clinical, and therapeutic relevance for major depression.

Results

Cohort analyses: phenotype validation. We identified seven cohorts that used a range of methods to ascertain cases with major depression (Table 1 and Supplementary Tables 1–3). The methods used by these cohorts were thoroughly reviewed, drawing on the breadth of expertise in the PGC, and we assessed the comparability of the cohorts using genomic data. We use 'MDD' to refer to directly evaluated subjects meeting standard criteria for major depressive disorder and use 'major depression' where case status was determined using alternative methods as well as to the phenotype from the full meta-analysis.

We evaluated the comparability of the seven cohorts by estimating the common variant genetic correlations (r_g) between them. These analyses supported the comparability of the seven cohorts (Supplementary Table 3), as the weighted mean r_g was 0.76 (s.e. = 0.03). The high genetic correlations between the 23andMe and other cohorts are notable. While there was no statistical evidence of heterogeneity in the r_g estimates for pairs of cohorts ($P = 0.13$), the estimate was statistically different from 1, which may reflect etiological heterogeneity. This estimate can be benchmarked against the slightly larger weighted mean r_g between schizophrenia cohorts of 0.84 (s.e. = 0.05)[21].

Given the positive evidence of the genetic comparability of these cohorts, we completed a genome-wide association meta-analysis of 9.6 million imputed SNPs in 135,458 MDD and major depression cases and 344,901 controls (Fig. 1). There was no evidence of residual population stratification[24] (LD score regression intercept = 1.018, s.e. = 0.009). We estimated h^2_{SNP} to be 8.7% (s.e. = 0.004, liability scale, assuming lifetime risk of 0.15; Supplementary Fig. 1 and Supplementary Table 3b), and note that this is about one-quarter of the h^2 estimated from twin or family studies[9]. This fraction is somewhat lower than that of other complex traits[18] and is plausibly due to etiological heterogeneity (reflecting the mean $r_g < 1$ between cohorts).

To evaluate the impact of combining major depression cohorts that used different ascertainment methods, we undertook a series of genetic risk score (GRS) prediction analyses to demonstrate the validity of our genome-wide association results for clinical MDD (Fig. 2). Notably, the variance explained in out-of-sample prediction increased with the size of the genome-wide association discovery cohort (Fig. 2a), with the GRS from the full discovery

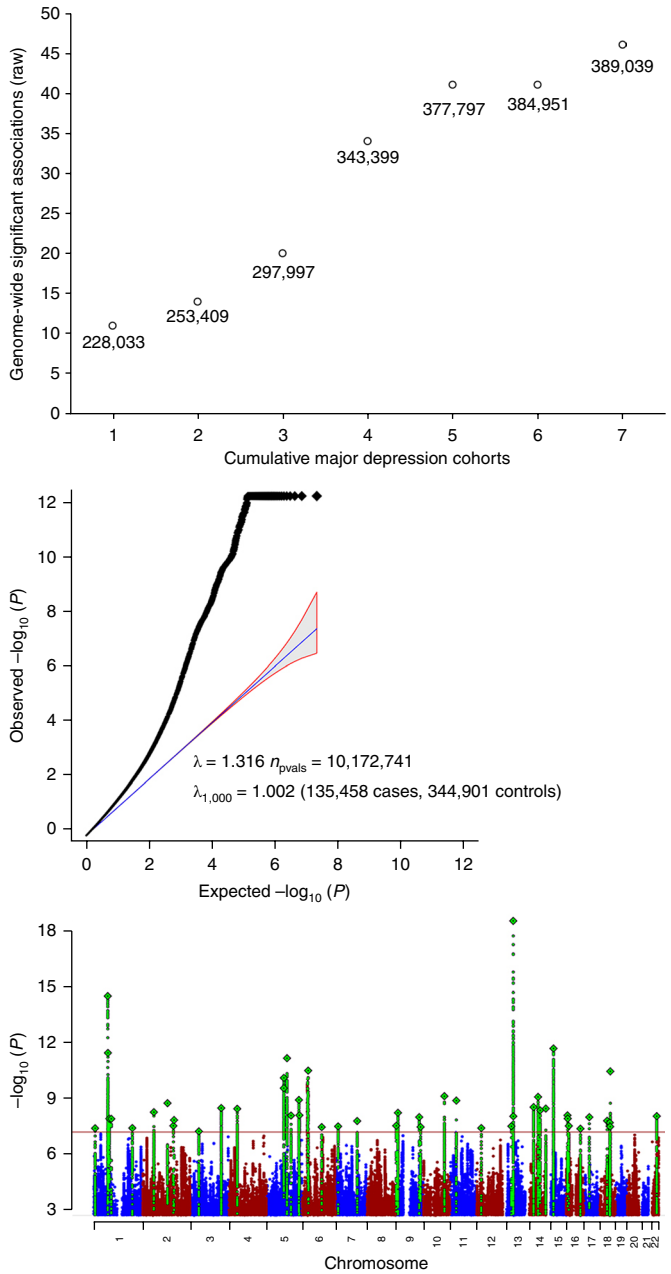

Fig. 1 | Results of genome-wide association meta-analysis of seven cohorts for major depression. a, Relationship between adding cohorts and the number of genome-wide significant genomic regions (before the vetting used to define the final 44 regions). Beginning with the largest cohort (cohort 1 on the *x* axis), we added the next largest cohort (cohort 2) until all cohorts were included (7 cohorts). The number next to each point is the total effective sample size, equivalent to the sample size where the numbers of cases and controls are equal. **b**, Association test quantile–quantile plot showing a marked departure from the null model of no associations (*y* axis truncated at 10^{-12}). **c**, Manhattan plot for association tests from meta-analysis of 135,458 major depression cases and 344,901 controls, with the *x* axis showing genomic position (chromosomes 1–22 plus the X chromosome) and the *y* axis showing statistical significance as $-\log_{10}(P)$ *z* statistics; the threshold for significance accounting for multiple testing is shown by the red horizontal line ($P = 5 \times 10^{-8}$).

sample meta-analysis explaining 1.9% of variance in liability (Fig. 2a, Supplementary Fig. 2, and Supplementary Table 4). For any randomly selected case and control, GRS ranked cases higher than controls with probability of 0.57 and the odds ratio of MDD for those in the tenth versus first GRS decile (OR = 10) was 2.4 (Fig. 2b and Supplementary Table 4). GRS analyses in other disorders (for example, schizophrenia[25]) have shown that the mean GRS increases with clinical severity in cases. We found a significantly higher major depression GRS in those with more severe MDD, as measured in different ways (Fig. 2c). Last, because around one-half of the major depression cases were identified by self-report (i.e., diagnosis or treatment for clinical depression by a medical professional), we further evaluated the comparability of the 23andMe cohort with the other cohorts (full meta-analysis excluding 23andMe, 'FMex23andMe') as detailed in Fig. 2c, Supplementary Table 5, and the Supplementary Note. Taken together, we interpret these results as supporting this meta-analysis of GWAS for these seven cohorts.

Implications for the biology of major depression. Our meta-analysis of seven MDD and major depression cohorts identified 44 independent loci that were statistically significant ($P < 5 \times 10^{-8}$), statistically independent of any other signal[26], and supported by multiple SNPs. This number supports our prediction that genome-wide association discovery in major depression would require about five times more cases than for schizophrenia (lifetime risk ~1% and h^2 ~0.8) to achieve approximately similar power[27]. Of these 44 loci, 30 are new and 14 were significant in a prior study of MDD or depressive symptoms. The overlap of our findings with prior reports was as follows: 1 of 1 with CHARGE depressive symptom[14], 1 of 2 overlap with SSGAC depressive symptom[16], and 12 of 15 overlap with Hyde et al.[28]. There are few trans-ancestry comparisons for major depression, so we contrasted these European results with the Han Chinese CONVERGE study[15] (Supplementary Note). The loci identified in CONVERGE are uncommon in Europeans (rs12415800, 0.45 versus 0.02; rs35936514, 0.28 versus 0.06) and were not significant in our analysis.

Table 2 lists genes in or near the lead SNP in each region, regional plots are in Supplementary Data 1, and Supplementary Tables 6 and 7 provide summaries of available information about the biological functions of the genes in each region. In the Supplementary Note, we review four key genes in more detail: *OLFM4* and *NEGR1* (notable for reported associations with obesity and body mass index[29–34]), *RBFOX1* (notable for independent associations at both the 5′ and 3′ ends, a splicing regulator[35,36], with a functional role that may be consistent with chronic hypothalamic–pituitary–adrenal axis hyperactivation reported in MDD[37]), and *LRFN5* (notable for its role in presynaptic differentiation[38,39] and neuroinflammation[40]).

Gene-wise analyses identified 153 significant genes after controlling for multiple comparisons (Supplementary Table 7). Many of these genes were in the extended major histocompatibility complex (MHC) region (45 of 153), and their interpretation is complicated by high linkage disequilibrium (LD) and gene density. In addition to the genes discussed above, other notable and significant genes outside of the MHC region include multiple potentially 'druggable' targets that suggest connections of the pathophysiology of MDD to neuronal calcium signaling (*CACNA1E* and *CACNA2D1*), dopaminergic neurotransmission (*DRD2*, a principal target of antipsychotics), glutamate neurotransmission (*GRIK5* and *GRM5*), and presynaptic vesicle trafficking (*PCLO*).

Finally, comparison of the major depression loci with 108 loci for schizophrenia[19] identified 6 shared loci. Many SNPs in the extended MHC region are strongly associated with schizophrenia, but implication of the MHC region is new for major depression. Another example is *TCF4* (transcription factor 4), which is strongly associated with schizophrenia but was not previously associated with MDD. TCF4 is essential for normal brain development, and rare mutations in *TCF4* cause Pitt–Hopkins syndrome, which includes autistic features[41]. The GRS calculated from the schizophrenia

Table 1 | Brief description of the seven MDD or major depression cohorts used in the meta-analysis

Sample	Country	Case ascertainment	Cases	Controls
PGC29[13,a]	Various	Structured diagnostic interviews[b]	16,823	25,632
deCODE[13]	Iceland	National inpatient electronic records	1,980	9,536
GenScotland[78,79]	UK	Structured diagnostic interview	997	6,358
GERA[80]	USA	Kaiser Permanente Northern California Healthcare electronic medical records (1995–2013)	7,162	38,307
iPSYCH[81]	Denmark	National inpatient electronic records	18,629	17,841
UK Biobank[82] (pilot data release)	UK	From self-reported MDD symptoms or treatment or electronic records[69]	14,260	15,480
23andMe[28] (discovery sample)[c]	USA	Self-reported diagnosis or treatment for clinical depression by a medical professional	75,607	231,747
Total			135,458	344,901

[a]Nineteen samples in addition to the ten samples published in the first PGC-MDD paper[13]. [b]One sample used natural language processing of electronic medical records followed by expert diagnostic review. [c]In Hyde et al.[28], SNPs in 15 genomic regions met genome-wide significance in the combined discovery and replication samples and 11 regions achieved genome-wide significance in the discovery sample made available to the research community and used here. More details are provided in Supplementary Tables 1–3.

genome-wide association results explained 0.8% of the variance in liability of MDD (Fig. 2c).

Implications from integration of functional genomic data. Results from 'omic' studies of functional features of cells and tissues are necessary to understand the biological implications of the results of GWAS for complex disorders[42]. To further elucidate the biological relevance of the major depression findings, we integrated the results with functional genomic data. First, using enrichment analyses, we compared the major depression GWAS findings to bulk tissue mRNA-seq from Genotype-Tissue Expression (GTEx) data[43]. Only brain samples showed significant enrichment (Fig. 3a), and the three tissues with the most significant enrichments were all cortical. Prefrontal cortex and anterior cingulate cortex are important for higher-level executive functions and emotional regulation, which are often impaired in MDD. Both of these regions were implicated in a large meta-analysis of brain magnetic resonance imaging (MRI) findings in adult MDD cases[44]. Second, given the predominance of neurons in the cortex, we confirmed that the major depression genetic findings connect to genes expressed in neurons but not oligodendrocytes or astrocytes (Fig. 3b)[45]. Given the different methods used by the seven MDD/major depression cohorts in this study, demonstration of enrichment of association signals in the brain regions expected to be most relevant to MDD provides independent support for the validity of our approach.

Third, we used partitioned LD score regression[46] to evaluate the enrichment of the major depression genome-wide association findings in over 50 functional genomic annotations (Fig. 3c and Supplementary Table 8). The major finding was the significant enrichment of h^2_{SNP} in genomic regions conserved across 29 Eutherian mammals[47] (20.9-fold enrichment, $P = 1.4 \times 10^{-15}$). This annotation was also the most enriched for schizophrenia[46]. We could not evaluate regions conserved in primates or human 'accelerated' regions, as there were too few for confident evaluation[47]. The other enrichments implied regulatory activity and included open chromatin in human brain and an epigenetic mark of active enhancers (H3K4me1). Notably, exonic regions did not show enrichment, suggesting that, as with schizophrenia[17], genetic variants that change exonic sequences may not have a large role in major depression. We found no evidence that Neanderthal introgressed regions were enriched for major depression genome-wide association findings[48].

Fourth, we applied methods to integrate genome-wide association SNP results with those from gene expression and methylation quantitative trait locus (eQTL and meQTL) studies. SMR[49] analysis identified 13 major depression–associated SNPs with strong evidence that they control local gene expression in one or more tissues and 9 with strong evidence that they control local DNA methylation (Supplementary Table 9 and Supplementary Data 2). A transcriptome-wide association study[50] applied to data from the dorsolateral prefrontal cortex[51] identified 17 genes where major depression–associated SNPs influenced gene expression (Supplementary Table 10). These genes included *OLFM4* (discussed above).

Fifth, we added additional data types to attempt to improve understanding of individual loci. For the intergenic associations, we evaluated total-stranded RNA-seq data from human brain and found no evidence for unannotated transcripts in these regions. A particularly important data type is assessment of DNA–DNA interactions, which can localize a genome-wide association finding to a specific gene that may be nearby or hundreds of kilobases away[52–54]. We integrated the major depression results with 'easy Hi-C' data from brain cortical samples (3 adult, 3 fetal, >1 billion reads each). These data clarified three associations. The statistically independent associations in *NEGR1* (rs1432639, $P = 4.6 \times 10^{-15}$) and over 200 kb away (rs12129573, $P = 4.0 \times 10^{-12}$) both implicate *NEGR1* (Supplementary Fig. 3a), the former likely due to the presence of a reportedly functional copy number polymorphism (see Supplementary Note) and the presence of intergenic loops. The latter association has evidence of DNA looping interactions with *NEGR1*. The association in *SOX5* (rs4074723) and the two statistically independent associations in *RBFOX1* (rs8063603 and rs7198928, $P = 6.9 \times 10^{-9}$ and 1.0×10^{-8}) had only intragenic associations, suggesting that the genetic variation in the regions of the major depression associations act locally and can be assigned to these genes. In contrast, the association in *RERE* (rs159963, $P = 3.2 \times 10^{-8}$) could not be assigned to *RERE* as it may contain super-enhancer elements given its many DNA–DNA interactions with many nearby genes (Supplementary Fig. 3b).

Implications based on the roles of sets of genes. A parsimonious explanation for the presence of many significant associations for a complex trait is that the different associations are part of a higher-order grouping of genes[55]. These could be a biological pathway or a collection of genes with a functional connection. Multiple methods allow evaluation of the connection of major depression genome-wide association results to sets of genes grouped by empirical or predicted function (pathway or gene set analysis).

Full pathway analyses are in Supplementary Table 11, and 19 pathways with false discovery rate q values <0.05 are summarized in Fig. 4. The major groupings of significant pathways were as follows: RBFOX1, RBFOX2, RBFOX3, or CELF4 regulatory networks; genes whose mRNAs are bound by FMRP; synaptic genes; genes

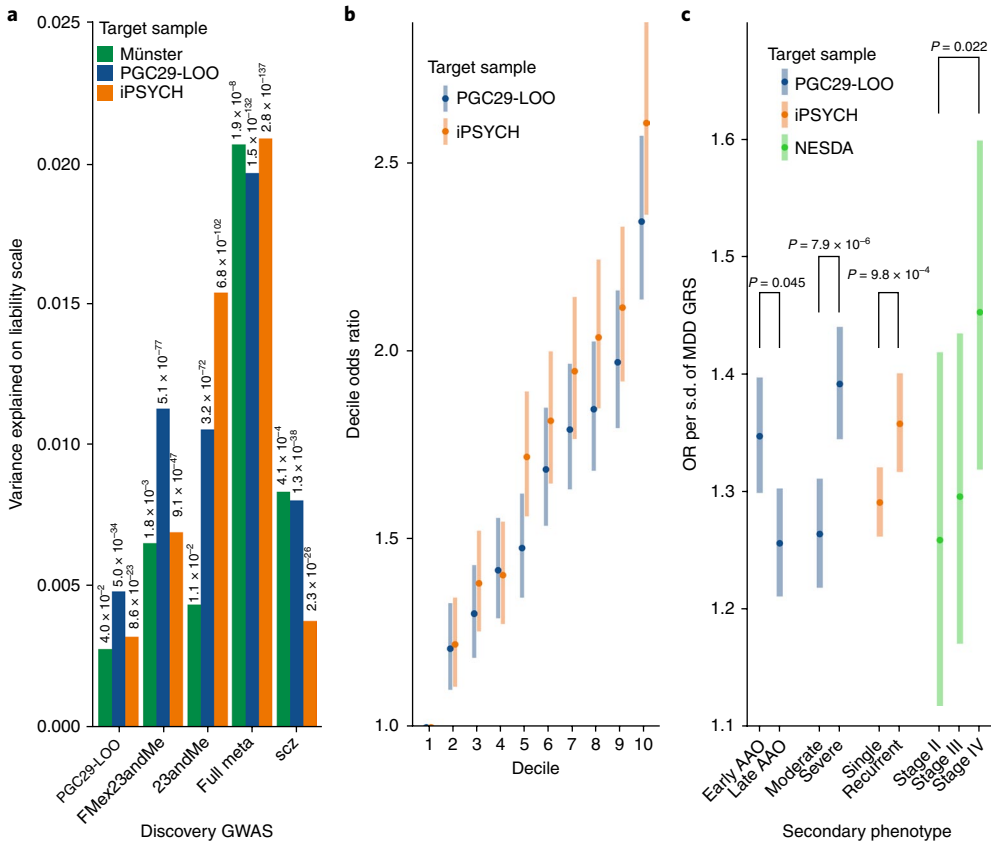

Fig. 2 | Genetic risk score prediction analyses into PGC29 MDD target samples. a, Variance explained (liability scale) based on different discovery samples for three target samples: PGC29 (16,823 cases, 25,632 controls), iPSYCH (a nationally representative sample of 18,629 cases and 17,841 controls), and a clinical cohort from Münster not included in the genome-wide association analysis (845 MDD inpatient cases, 834 controls). For PGC29-LOO, the target sample was one of the PGC29 samples with the discovery sample being the remaining 28 PGC29 samples, hence representing leave-one-out (LOO) analysis. **b**, Odds ratios of major depression per GRS decile relative to the first decile for the iPSYCH and PGC29 target samples. **c**, Odds ratios of major depression in GRS s.d.: PGC29-LOO, 3,950 early-onset versus 3,950 late-onset cases; PGC29-LOO, 4,958 severe versus 3,976 moderate cases defined by count of endorsed MDD symptom criteria; iPSYCH, 5,574 cases of recurrent MDD versus 12,968 single-episode cases; and NESDA from PGC29, severity defined as chronic/unremitting MDD, 610 'stage IV' cases versus 499 'stage II' or 332 first-episode MDD cases[77] . Error bars represent 95% confidence intervals. Logistic regression association test *P* values are shown in the target sample for the GRS generated from SNPs with $P < 0.05$ in the discovery sample. FMex23andMe, full meta-analysis excluding 23andMe; scz, schizophrenia[19].

involved in neuronal morphogenesis; genes involved in neuron projection; genes associated with schizophrenia (at $P < 10^{-4}$)[19]; genes involved in central nervous system (CNS) neuron differentiation; genes encoding voltage-gated calcium channels; genes involved in cytokine and immune response; and genes known to bind to the retinoid X receptor. Several of these pathways are implicated by GWAS of schizophrenia and by rare exonic variation of schizophrenia and autism[56,57] and immediately suggest shared biological mechanisms across these disorders.

A key issue for common variant GWAS is their relevance for pharmacotherapy. We conducted gene set analysis that compared the major depression genome-wide association results to targets of antidepressant medications defined by pharmacological studies[58] and found that 42 sets of genes encoding proteins bound by antidepressant medications were highly enriched for smaller major depression association *P* values than expected by chance (42 drugs, rank enrichment test $P = 8.5 \times 10^{-10}$). This finding connects our major depression genomic findings to MDD therapeutics and suggests the salience of these results for new lead compound discovery for MDD[59].

Implications based on relationships with other traits. Prior epidemiological studies associated MDD with many other diseases and traits. Because of limitations inherent to observational studies, understanding whether a phenotypic correlation is potentially causal or if it results from reverse causation or confounding is generally difficult. Genetic studies now offer complementary strategies to assess whether a phenotypic association between MDD and a risk factor or a comorbidity is mirrored by a nonzero r_g (common variant genetic correlation) and, for some of these, evaluate the potential causality of the association given that exposure to genetic risk factors begins at conception.

We used LD score regression to estimate the r_g of major depression with 221 psychiatric disorders, medical diseases, and human traits[22,60]. Supplementary Table 12 contains the full results, and Table 3 shows the r_g values with false discovery rates <0.01. First, the r_g values were very high between our major depression genome-wide association results and those from two studies of current depressive symptoms. Both correlations were close to 1 (the samples in one report overlapped partially with this meta-analysis[16], but the samples from the other did not[14]).

Second, we found significant positive genetic correlations between major depression and every psychiatric disorder assessed along with smoking initiation. This is a comprehensive and well-powered evaluation of the relationship of MDD with other psychiatric disorders, and these results indicate that the common genetic

Chr. (chromosome) and region (boundaries in Mb; hg19) are shown, defined by the locations of SNPs with $P < 1 \times 10^{-5}$ and LD $r^2 > 0.1$ with the most strongly associated SNP (logistic regression; the lowest *P* value in the region listed is not corrected for multiple testing), whose location is given in base pairs. In three regions, a second SNP fulfilled the filtering criteria and was followed up with conditional analyses: chr. 1, conditional analysis selected only rs1432639 as significant, with $P = 2.0 \times 10^{-4}$ for rs12134600 after fitting rs1432639; chr. 5, conditional analysis showed two independent associations selecting rs247910 and rs10514301 as the most strongly associated SNPs; chr. 10, conditional analysis selected only rs61867293 with $P = 8.6 \times 10^{-5}$ for rs1021363 after conditioning on rs61867293. For each of the 47 SNPs, there was at least one additional genome-wide significant SNP in the cluster of surrounding SNPs with low *P* values. Chromosome X was analyzed but had no findings that met genome-wide significance. Entries in the "Prev." column indicate which of four previous studies identified genome-wide significant associations in a region: H, Hyde et al.[28], 23andMe genome-wide association of self-reported clinical depression (the discovery sample overlaps with this paper); O, Okbay et al.[16], meta-analysis of genome-wide association of MDD, depressive symptoms, psychological well-being, and neuroticism (includes many PGC29 samples); S, PGC report on 108 schizophrenia-associated loci[19]; C, CHARGE Consortium meta-analysis of depressive symptoms[14]. The "Gene context" column shows the distances between the peak SNP and the closest genes; brackets indicate that the peak SNP was within that gene. The closest genes upstream (taking strand into account; a negative number indicates distance in base pairs between the peak SNP and the nearest gene boundary) and downstream (positive distance in base pairs) are also shown if there was a flanking gene within 200 kb. The name of the closest gene is in brackets. Note that it is generally not known whether associated SNPs have biological effects on these or other more distant genes. A1/A2, the two alleles (or insertion–deletion) at each SNP; A1 was tested for association and its OR (odds ratio) and s.e. are shown; Freq., the frequency of A1 in controls across all cohorts.

variants that predispose to MDD overlap substantially with those for adult- and childhood-onset psychiatric disorders, although they remain substantially distinct as well.

Third, the common variant genetic architecture of major depression was positively correlated with multiple measures of sleep quality (daytime sleepiness, insomnia, and tiredness). The first two of these correlations used UK Biobank data with people endorsing major depression or other major psychiatric disorders, shift workers, and those taking hypnotics excluded. This pattern of correlations combined with the importance of sleep and fatigue in major depression (two criteria for MDD) suggests a close and potentially profound mechanistic relationship. Major depression also had a strong genetic correlation with neuroticism (a personality dimension assessing the degree of emotional instability); this is consistent with the literature showing a close interconnection of MDD and this personality trait. The strong negative r_g with subjective well-being underscores the capacity of major depression to impact human health.

Finally, major depression had significant negative genetic correlations with data from two studies of educational attainment, which while often considered at the genetic level as proxy measures of intelligence also likely includes more complex personality constructs. With this in mind, it is relevant to note that the r_g between major depression and IQ[61] was not significantly different from zero, despite the r_g between years of education and IQ being 0.7, implying complex relationships between these traits worthy of future investigation. We also found significant positive correlations with multiple measures of adiposity, relationship to female reproductive behavior (decreased age at menarche, age at first birth, and increased number of children), and positive correlations with coronary artery disease and lung cancer.

We used bidirectional Mendelian randomization (MR) to investigate the relationships between four traits genetically correlated with major depression: years of education (EDY)[62], body mass index (BMI)[29], coronary artery disease (CAD)[63], and schizophrenia[19]. These traits were selected because all of the following were true: they were phenotypically associated with MDD, had significant r_g with MDD, and had >30 independent genome-wide significant associations from large GWAS. We report GSMR[64] results but obtained qualitatively similar results with other MR methods (Supplementary Fig. 4 and Supplementary Table 13). MR analyses provided evidence for a 1.12-fold increase in major depression per s.d. of BMI ($P_{GSMR} = 1.2 \times 10^{-7}$) and a 0.84-fold decrease in major depression per s.d. of EDY ($P_{GSMR} = 2.3 \times 10^{-6}$). There was no evidence of reverse causality of major depression for BMI ($P_{GSMR} = 0.53$) or EDY ($P_{GSMR} = 0.11$). For BMI, there was some evidence of pleiotropy, as six BMI-associated SNPs were excluded by the HEIDI outlier test including SNPs near *OLFM4* and *NEGR1*. Thus, these results are consistent with EDY and BMI as either causal risk factors or correlated with causal risk factors for major depression. These results provide hypotheses for future research to understand these potentially directional relationships.

For CAD, the MR analyses were not significant when considering major depression as an outcome ($P_{GSMR} = 0.30$) or as an exposure ($P_{GSMR} = 0.12$); however, the high standard error of the estimates using MDD SNP instruments implies that this analysis should be revisited when more major genome-wide significant SNP instruments for depression become available from future GWAS.

We used MR to investigate the relationship between major depression and schizophrenia. Although major depression had positive r_g with many psychiatric disorders, only schizophrenia had

All genetic correlations (r_g) estimated using bivariate LDSC applied to major depression genome-wide association results are in Supplementary Table 12. Shown above are the r_g values of major depression with false discovery rate (FDR) < 0.01 (FDR estimated for 221 genetic correlations; H_0: $r_g = 0$). Thematically related traits are indicated by bold font. iPSYCH is a nationally representative cohort based on blood spots collected at birth. Within iPSYCH, r_g with ADHD was 0.58 (s.e. = 0.050) and with ASD was 0.51 (s.e. = 0.07); these values are larger than those listed above and are inconsistent with artifactual correlations. h^2_{SNP} is shown to aid interpretation as high r_g in the context of high h^2_{SNP} is more noteworthy than when h^2_{SNP} is low. [a]Self-reported daytime sleepiness and insomnia from UK Biobank excluding subjects with major depression, other psychiatric disorders (bipolar disorder, schizophrenia, autism, intellectual disability), shift workers, and those taking hypnotics.

sufficient associations for MR analyses. We found significant bidirectional correlations in SNP effect sizes for schizophrenia loci in major depression ($P_{GSMR} = 1.1 \times 10^{-40}$) and for major depression loci in schizophrenia ($P_{GSMR} = 1.5 \times 10^{-11}$). These results suggest that the major depression–schizophrenia r_g of 0.34 is consistent with

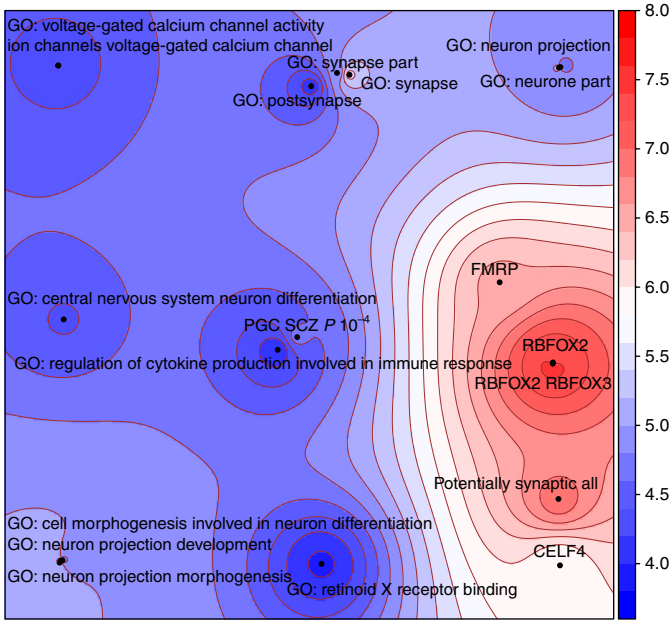

Fig. 4 | Generative topographic mapping of the 19 significant pathway results. The average position of each pathway on the map is represented by a point. The map is colored by the $-\log_{10}$ *P* value obtained using MAGMA. The *x* and *y* coordinates were obtained from a kernel generative topographic mapping algorithm (GTM) that reduces high-dimensional gene sets to a 2D scatterplot by accounting for gene overlap between gene sets. Each point represents a gene set. Nearby points are more similar in gene overlap than more distant points. The color surrounding each point (gene set) corresponds to significance according to the scale on the right. The significant pathways (Supplementary Table 11) fall into nine main clusters as described in the text.

partially shared biological pathways being causal for both disorders. Although it is plausible that diagnostic misclassification/ambiguity (for example, misdiagnosis of MDD as schizoaffective disorder) could contaminate these analyses, levels of misclassification would need to be implausibly high (30% unidirectional, 15% bidirectional) to result in an r_g of ~0.3[65].

All MR analyses were repeated after excluding the 23 and Me cohort, and the pattern of the results was the same (Supplementary Table 13).

Discussion

The nature of severe depression has been discussed for millennia[66]. This genome-wide association meta-analysis is among the largest ever conducted in psychiatric genetics and provides a body of results that helps refine the fundamental basis of major depression.

In conducting this meta-analysis of major depression, we employed a pragmatic approach by including cohorts that met empirical criteria for sufficient genetic and phenotypic similarity. Our approach was cautious, clinically informed, guided by empirical data, and selective (for example, we did not include cohorts with bipolar disorder (which requires MDD), depressive symptoms, neuroticism, or well-being). Approximately 44% of all major depression cases were assessed using traditional methods (PGC29, GenScot), treatment registers (iPSYCH, GERA; such approaches have been extensively used to elucidate the epidemiology of major depression), or a combination of methods (deCODE, UK Biobank), whereas ~56% of cases were from 23andMe (via self-report)[28]. Multiple lines of genetic evidence supported conducting meta-analysis of these seven cohorts (for example, out-of-sample prediction, sign tests, and genetic correlations).

However, our approach may be controversial to some readers given the unconventional reliance on self-report of major depression. We would reframe the issue: we hypothesize that brief methods of assessing major depression are informative for the genetics of MDD. We present a body of results that is consistent with this hypothesis. Even if unconventional, our hypothesis is testable and falsifiable, and we invite and welcome empirical studies to further support or refute this hypothesis.

Our results lead us to draw some broad conclusions. First, major depression is a brain disorder. Although this is not unexpected, some past models of MDD have had little or no place for heredity or biology. The genetic results best match gene expression patterns in the prefrontal and anterior cingulate cortex, anatomical regions that show differences between MDD cases and controls. The genetic findings implicated neurons (not microglia or astrocytes), and we anticipate more detailed cellular localization when sufficient single-cell and single-nucleus RNA-seq datasets become available[67].

Second, the genetic associations for major depression (as with schizophrenia)[46] tend to occur in genomic regions conserved across a range of placental mammals. Conservation suggests important functional roles. Notably, our analyses did not implicate exons or coding regions.

Third, the results also implicated developmental gene regulatory processes. For instance, the genetic findings pointed at the splicing regulator *RBFOX1* (the presence of two independent genetic associations in *RBFOX1* strongly suggests that it is the relevant gene). Gene set analyses implicated genes containing binding sites to the protein product of *RBFOX1*, and this gene set is also significantly enriched for rare exonic variation in autism and schizophrenia[56,57]. These analyses highlight the potential importance of splicing to generate alternative isoforms; risk for major depression may be mediated not by changes in isolated amino acids but rather by changes in the proportions of isoforms coming from a gene, given that isoforms often have markedly different biological functions[68,69]. These convergent results provide possible clues to a biological mechanism common to multiple severe psychiatric disorders that merits future research.

Fourth, in the most extensive analysis of the genetic 'connections' of major depression with a wide range of disorders, diseases, and human traits, we found significant positive genetic correlations with measures of body mass and negative genetic correlations with years of education, while showing no evidence of genetic correlation with IQ. MR analysis results are consistent with both BMI and years of education being causal, or correlated with causal, risk factors for major depression, and our results provide hypotheses and motivation for more detailed prospective studies, as currently available data may not provide insight about the fundamental driver or drivers of causality. The underlying mechanisms are likely more complex, as it is difficult to envision how genetic variation in educational attainment or body mass alters risk for MDD without invoking an additional mechanistic component. While the significant MR analyses need further investigations to fully understand, the negative MR results provide important evidence that there is not a direct causal relationship between MDD and subsequent changes in body mass or education years. If such associations are observed in epidemiological or clinical samples, then other factors must drive the association.

Fifth, we found significant positive correlations of major depression with all psychiatric disorders that we evaluated, including disorders prominent in childhood. This pattern of results indicates that the current classification scheme for major psychiatric disorders does not align well with the underlying genetic basis of these disorders. Currently, only schizophrenia has a sufficient number of genome-wide significant loci to conduct MR analysis, but the bidirectionally significant MR results are consistent with a shared biological basis for major depression and schizophrenia.

The dominant psychiatric nosological systems were principally designed for clinical utility and are based on data that emerge during human interactions (i.e., observable signs and reported symptoms) and not objective measurements of pathophysiology. MDD is frequently comorbid with other psychiatric disorders, and the phenotypic comorbidity has an underlying structure that reflects shared origins (as inferred from factor analyses and twin studies)[70–73]. Our genetic results add to this knowledge: major depression is not a discrete entity at any level of analysis. Rather, our data strongly suggest the existence of biological processes common to major depression and schizophrenia (and likely other psychiatric disorders).

Finally, as expected, we found that major depression had modest h^2_{SNP} (8.7%), as it is a complex malady with both genetic and environmental determinants. We found that major depression has a very high genetic correlation with proxy measures that can be briefly assessed. Lifetime major depressive disorder requires a constellation of signs and symptoms whose reliable scoring requires an extended interview with a trained clinician. However, the common variant genetic architecture of lifetime major depression in these seven cohorts (containing many subjects medically treated for MDD) has strong overlap with that of current depressive symptoms in general community samples. Similar relationships of clinically defined ADHD or autism with quantitative genetic variation in the population have been reported[74,75]. The 'disorder-versus-symptom' relationship has been debated extensively[76], but our data indicate that the common variant genetic overlap is very high. This finding has important implications.

One implication is for future genetic studies. In a first phase, it should be possible to elucidate the bulk of the common variant genetic architecture of MDD using a cost-effective shortcut—large studies of genotyped individuals who complete online self-report assessments of lifetime MDD (a sample size approaching 1 million MDD cases may be achievable by 2020). Use of online assessment could allow for recording of a broad range of phenotypes including comorbidities and putative environmental exposures, but with the key feature being large samples with consistently assessed measures. In a second phase, with a relatively complete understanding of the genetic basis of major depression, one could then evaluate smaller samples of carefully phenotyped individuals with MDD to understand the clinical importance of the genetic results. Subsequent empirical studies may show that it is possible to stratify MDD cases at first presentation to identify individuals at high risk for recurrence, poor outcome, poor treatment response, or who might subsequently develop a psychiatric disorder requiring alternative pharmacotherapy (for example, schizophrenia or bipolar disorder). This could form a cornerstone of precision medicine in psychiatry.

In summary, this genome-wide association meta-analysis of 135,438 MDD and major depression cases and 344,901 controls identified 44 loci. An extensive set of companion analyses provide insights into the nature of MDD as well as its neurobiology, therapeutic relevance, and genetic and biological interconnections to other psychiatric disorders. Comprehensive elucidation of these features is the primary goal of our genetic studies of MDD.

Acknowledgements

Full acknowledgments are in the Supplementary Note. We are deeply indebted to the investigators who comprise the PGC, and to the hundreds of thousands of subjects who have shared their life experiences with PGC investigators. A full list of funding is in the Supplementary Note. Major funding for the PGC is from the US National Institutes of Health (U01 MH109528 and U01 MH109532). Statistical analyses were carried out on the NL Genetic Cluster Computer (http://www.geneticcluster.org/) hosted by SURFsara. The iPSYCH team acknowledges funding from the Lundbeck Foundation (grants R102-A9118 and R155-2014-1724), the Stanley Medical Research Institute, the European Research Council (project 294838), the Novo Nordisk Foundation for supporting the Danish National Biobank resource, and Aarhus and Copenhagen Universities and University Hospitals, including support to the iSEQ Center, the GenomeDK HPC facility, and the CIRRAU Center. This research has been conducted using the UK Biobank Resource (see URLs), including applications 4844 and 6818. Finally, we thank the members of the eQTLGen Consortium for allowing us to use their very large eQTL database ahead of publication. Its members are listed in Supplementary Table 14.

Some data used in this study were obtained from dbGaP (see URLs). dbGaP accession phs000021: funding support for the Genome-Wide Association of Schizophrenia Study was provided by the National Institute of Mental Health (R01 MH67257, R01 MH59588, R01 MH59571, R01 MH59565, R01 MH59587, R01 MH60870, R01 MH59566, R01 MH59586, R01 MH61675, R01 MH60879, R01 MH81800, U01 MH46276, U01 MH46289, U01 MH46318, U01 MH79469, and U01 MH79470), and the genotyping of samples was provided through the Genetic Association Information Network (GAIN). Samples and associated phenotype data for the Genome-Wide Association of Schizophrenia Study were provided by the Molecular Genetics of Schizophrenia Collaboration (principal investigator P. V. Gejman, Evanston Northwestern Healthcare (ENH) and Northwestern University, Evanston, IL, USA). dbGaP accession phs000196: this work used in part data from the NINDS dbGaP database from the CIDR:NGRC PARKINSON'S DISEASE STUDY. dbGaP accession phs000187: High-Density SNP Association Analysis of Melanoma: Case–Control and Outcomes Investigation. Research support to collect data and develop an application to support this project was provided by P50 CA093459, P50 CA097007, R01 ES011740, and R01 CA133996 from the NIH.

Methods

PGC29 cohort. Our analysis was anchored in a genome-wide association mega-analysis of 29 samples of European ancestry (16,823 MDD cases and 25,632 controls). Supplementary Table 1 summarizes the source and inclusion/exclusion criteria for cases and controls for each sample. All PGC29 samples passed a structured methodological review by MDD assessment experts (D.F.L. and K.S.K.). Cases were required to meet international consensus criteria (DSM-IV, ICD-9, or ICD-10)[97–99] for a lifetime diagnosis of MDD established using structured diagnostic instruments from assessments by trained interviewers, clinician-administered checklists, or medical record review. All cases met standard criteria for MDD, were directly interviewed (28/29 samples), or had medical record review by an expert diagnostician (1/29 samples), and most were ascertained from clinical sources (19/29 samples). Controls in most samples were screened for the absence of lifetime MDD (22/29 samples) and randomly selected from the population.

Additional cohorts. We critically evaluated six independent European-ancestry cohorts (118,635 cases and 319,269 controls). Supplementary Table 2 summarizes the source and inclusion/exclusion criteria for cases and controls for each cohort. These cohorts used a range of methods for assessing MDD or major depression. Most studies included here applied otherwise typical inclusion and exclusion criteria for both cases and controls (for example, excluding cases with lifetime bipolar disorder or schizophrenia and excluding controls with major depression).

Cohort comparability. Supplementary Table 3 summarizes the numbers of cases and controls in PGC29 and the six additional cohorts. The most direct and important way to evaluate the comparability of these cohorts for a genome-wide association meta-analysis is using SNP genotype data[22,24]. We used LD score (LDSC) regression (described below) to estimate h^2_{SNP} for each cohort (Supplementary Fig. 1 and Supplementary Table 3) and r_g for all pairwise combinations of the cohorts (Supplementary Table 3b) and to demonstrate no evidence of sample overlap. We used leave-one-sample-out GRSs, finding significant differences in case–control GRS distributions of the left-out sample for all but one PGC29 sample (Supplementary Table 4). For full details of the cohort comparability analyses including GRS analyses, see the Supplementary Note. In GRS analyses, the discovery sample was the genome-wide association sample that provided the allelic weightings for each SNP, used to generate a sum score for each individual in the independent target sample.

Genotyping and quality control. Genotyping procedures can be found in the primary reports for each cohort (summarized in Supplementary Table 3). Individual genotype data for all PGC29 samples, GERA, and iPSYCH were processed using the PGC ricopili pipeline (see URLs) for standardized quality control, imputation, and analysis[19]. The cohorts from deCODE, Generation Scotland, UK Biobank, and 23andMe were processed by the collaborating research teams using comparable procedures. SNPs and insertion–deletion polymorphisms were imputed using the 1000 Genomes Project multi-ancestry reference panel (see URLs)[100]. More detailed information on sample quality control is provided in the Supplementary Note.

LD score regression. LDSC was used to estimate h^2_{SNP} from genome-wide association summary statistics. Estimates of h^2_{SNP} on the liability scale depend on the assumed lifetime prevalence of MDD in the population (K), and we assumed $K = 0.15$ but also evaluated a range of estimates of K to explore sensitivity, including 95% confidence intervals (Supplementary Fig. 1). LDSC bivariate genetic correlations attributable to genome-wide SNPs (r_g) were estimated across all MDD and major depression cohorts and between the full cohort subjected to meta-analysis and other traits and disorders.

LDSC was also used to partition h^2_{SNP} by genomic features[24,46]. We tested for enrichment of h^2_{SNP} based on genomic annotations, partitioning h^2_{SNP} proportional to the base-pair length represented by each annotation. We used the 'baseline model', which consists of 53 functional categories. The categories are fully described elsewhere[46] and included conserved regions[47], USCC gene models (exons, introns, promoters, UTRs), and functional genomic annotations constructed using data from ENCODE[101] and the Roadmap Epigenomics Consortium[102]. We complemented these annotations by adding introgressed regions from the Neanderthal genome in European populations[103] and open chromatin regions from the brain dorsolateral prefrontal cortex. The open chromatin regions were obtained from an ATAC–seq experiment performed in 288 samples ($n = 135$ controls, 137 schizophrenia cases, 10 bipolar cases, and 6 affective disorder cases)[104]. Peaks called with MACS[105] (1% FDR) were retained if their coordinates overlapped in at least two samples. The peaks were recentered and set to a fixed width of 300 bp using the diffbind R package[106]. To prevent upward bias in heritability enrichment estimation, we added two categories created by expanding both the Neanderthal introgressed regions and open chromatin regions by 250 bp on each side.

We used LDSC to estimate r_g between major depression and a range of other disorders, diseases, and human traits[22]. The intent of these comparisons was to evaluate the extent of shared common variant genetic architectures to suggest hypotheses about the fundamental genetic basis of major depression (given its extensive comorbidity with psychiatric and medical conditions and its association with anthropometric and other risk factors). Subject overlap of itself does not bias r_g. These r_g values were mostly based on studies of independent subjects, and the estimates should be unbiased by confounding of genetic and non-genetic effects (except if there is genotype by environment correlation). When GWAS include overlapping samples, r_g remains unbiased but the intercept of the LDSC regression is an estimate of the correlation between the association statistics attributable to sample overlap. These calculations were done using the internal PGC genome-wide association library and with LD-Hub (see URLs)[60].

Integration of genome-wide association findings to tissue and cellular gene expression. We used partitioned LDSC to evaluate which somatic tissues were enriched for major depression heritability[107]. Gene expression data generated using mRNA-seq from multiple human tissues were obtained from GTEx v6p (see URLs). Genes for which <4 samples had at least one read count per million were discarded, and samples with <100 genes with at least one read count per million were excluded. The data were normalized, and a t statistic was obtained for each tissue by comparing the expression in each tissue with the expression of all other tissues with the exception of tissues related to the tissue of interest (for example, brain cortex versus all other tissues excluding other brain samples), using sex and age as covariates. A t statistic was also obtained for each tissue among its related tissues (for example, cortex versus all other brain tissues) to test which brain region was the most associated with major depression, also using sex and age as covariates. The top 10% of the genes with the most extreme t statistic were defined as tissue specific. The coordinates for these genes were extended by a 100-kb window and tested using LD score regression. Significance was obtained from the coefficient z score, which corrects for all other categories in the baseline model.

Lists of genes specifically expressed in neurons, astrocytes, and oligodendrocytes were obtained from Cahoy et al.[45]. As these experiments were done in mice, genes were mapped to human orthologous genes using Ensembl. The coordinates for these genes were extended by a 100-kb window and tested using LD score regression as for the GTEx tissue-specific genes.

We conducted eQTL lookups of the most associated SNPs in each region and report genome-wide association SNPs in LD ($r^2 > 0.8$) with the top eQTLs in the following datasets: eQTLGen Consortium (Illumina arrays in whole blood, $n = 14{,}115$), BIOS (RNA-seq in whole blood, $n = 2{,}116$)[108], NESDA/NTR (Affymetrix arrays in whole blood, $n = 4{,}896$)[109], GEUVADIS (RNA-seq in LCLs, $n = 465$)[110], Rosmap (RNA-seq in cortex, $n = 494$)[111], GTEx (RNA-seq in 44 tissues, $n > 70$)[43], and Common Mind Consortium (CMC; prefrontal cortex, Sage Synapse accession syn5650509, $n = 467$)[51].

We used SMR[49] to identify loci with strong evidence of causality via gene expression and DNA methylation (eQTLs and meQTLs). SMR analysis is limited to significant cis-SNP expression (FDR < 0.05) and SNPs with MAF >0.01 at a Bonferroni-corrected pSMR. Owing to LD, multiple SNPs may be associated with the expression of a gene, and some SNPs are associated with the expression of more than one gene. The aim of SMR is to prioritize variants and genes for subsequent studies, and a test for heterogeneity excludes regions that may harbor multiple causal loci (pHET < 0.05; a very conservative threshold). SMR analyses were conducted using eQTLs from the eQTLGen Consortium (whole blood), GTEx (11 brain tissues), and the CMC[43,51] as well as meQTLs from whole blood[112].

We conducted a transcriptome-wide association study[50] using precomputed expression reference weights for CMC data (5,420 genes with significant cis-SNP heritability) provided with the TWAS/FUSION software. The significance threshold was 0.05/5,420.

DNA looping using Hi-C. Dorsolateral prefrontal cortex (Brodmann area 9) was dissected from post-mortem samples from three adults of European ancestry (C.S.). Cerebra from three fetal brains were obtained from the NIH NeuroBiobank (see URLs; gestation age 17–19 weeks, African ancestry). We used 'easy Hi-C' to assess DNA chromatin (looping) interactions (Supplementary Note).

Gene-wise and pathway analyses. Our approach was guided by rigorous method comparisons conducted by PGC members[55,113]. P values quantifying the degree of association of genes and gene sets with MDD were generated using MAGMA (v1.06)[114]. MAGMA uses Brown's method to combine SNP P values and account for LD. We used Ensembl gene models for 19,079 genes, giving a Bonferroni-corrected P-value threshold of 2.6×10^{-6}. Gene set P values were obtained using a competitive analysis that tests whether genes in a gene set are more strongly associated with the phenotype than other gene sets. We used European-ancestry subjects from the 1000 Genomes Project (Phase 3 v5a, MAF ≥ 0.01)[115] for the LD reference. The gene window used was 35 kb upstream and 10 kb downstream to include regulatory elements.

Gene sets were from two main sources. First, we included gene sets previously shown to be important for psychiatric disorders (71 gene sets; for example, FMRP binding partners, de novo mutations, GWAS top SNPs, ion channels)[57,116,117]. Second, we included gene sets from MSigDB (v5.2)[118], which includes canonical pathways and Gene Ontology gene sets. Canonical pathways were curated from BioCarta, KEGG, Matrisome, the Pathway Interaction Database, Reactome, Sigma-Aldrich, Signaling Gateway, Signal Transduction KE, and SuperArray. Pathways containing from 10–10,000 genes were included.

To evaluate gene sets related to antidepressants, gene sets were extracted from the Drug–Gene Interaction database (DGIdb v.2.0)[119] and the NIMH Psychoactive Drug Screening Program Ki DB[120] downloaded in June 2016. The association of 3,885 drug gene sets with major depression was estimated using MAGMA (v1.6). The drug gene sets were ordered by *P* value, and the Wilcoxon–Mann–Whitney test was used to assess whether the 42 antidepressant gene sets in the dataset (ATC code N06A in the Anatomical Therapeutic Chemical Classification System) had a higher ranking than expected by chance.

One issue is that some gene sets contain overlapping genes, and these may reflect largely overlapping results. The pathway map was constructed using the kernel generative topographic mapping algorithm (k-GTM) as described by Olier et al.[121]. GTM is a probabilistic alternative to Kohonen maps: the kernel variant is used when the input is a similarity matrix. The GTM and k-GTM algorithms are implemented in GTMapTool (see URLs). We used the Jaccard similarity matrix of FDR-significant pathways as input for the algorithm, where each pathway is encoded by a vector of binary values representing the presence (1) or absence (0) of a gene. The parameters for the k-GTM algorithm are the square root of the number of grid points (k), the square root of the number of RBF functions (m), the regularization coefficient (l), the RBF width factor (w), and the number of feature space dimensions for the kernel algorithm (b). We set k equal to the square root of the number of pathways, m equal to the square root of k, $l = 1$ (default), $w = 1$ (default), and b equal to the number of principal components explaining 99.5% of the variance in the kernel matrix. The output of the program is a set of coordinates representing the average positions of pathways on a 2D map. The x and y axes represent the dimensions of a 2D latent space. The pathway coordinates and corresponding MAGMA *P* values were used to build the pathway activity landscape using the kriging interpolation algorithm implemented in the R gstat package.

Mendelian randomization. We conducted bidirectional MR[122] analysis for four traits: years of education (EDY)[62], body mass index (BMI)[29], coronary artery disease (CAD)[63], and schizophrenia (SCZ)[19]. We denote z as a genetic variant (a SNP) that is significantly associated with x, an exposure or putative causal trait for y (the disease/trait outcome). The effect size of x on y can be estimated using a two-step least-squares (2SLS)[123] approach: $\hat{b}_{xy} = \hat{b}_{zy}/\hat{b}_{zx}$, where $\hat{b}_{zx}$ is the estimated effect size for the SNP–trait association for the exposure trait and $\hat{b}_{zy}$ is the effect size estimated for the same SNP in the GWAS of the outcome trait.

We used generalized summary statistics–based MR (GSMR)[64] to estimate $\hat{b}_{xy}$ and its standard error from multiple SNPs associated with the exposure trait at a genome-wide significance level. We conducted bidirectional GSMR analyses for each pair of traits and report results after excluding SNPs that failed the HEIDI outlier heterogeneity test (which is more conservative than excluding SNPs that have an outlying association likely driven by locus-specific pleiotropy). GSMR is more powerful than inverse-weighted MR (IVW-MR) and MR-Egger because it takes account of the sampling variation of both $\hat{b}_{zx}$ and $\hat{b}_{zy}$. GSMR also accounts for residual LD between the clumped SNPs. For comparison, we also conducted IVW-MR and MR-Egger analyses[124]. More details are provided in the Supplementary Note.

Genome build. All genomic coordinates are given in NCBI Build 37/UCSC hg19.

Reporting Summary. Further information on experimental design is available in the Nature Research Reporting Summary linked to this article.

Data availability. The PGC's policy is to make genome-wide summary results public. Summary statistics for a combined meta-analysis of PGC29 with five of the six expanded samples (deCODE, Generation Scotland, GERA, iPSYCH, and UK Biobank) are available on the PGC website (see URLs). Results for 10,000 SNPs for all seven cohorts are also available on the PGC website.

Genome-wide association summary statistics for the Hyde et al. cohort (23andMe, Inc.) must be obtained separately. These can be obtained by qualified researchers under an agreement with 23andMe that protects the privacy of the 23andMe participants. Contact David Hinds (dhinds@23andme.com) to apply for access to the data. Researchers who have the 23andMe summary statistics can readily recreate our results by performing meta-analysis of the six-cohort results file with the Hyde et al. results file from 23andMe[28].

The availability of genotype data for PGC29 is described in Supplementary Table 15. For the expanded cohorts, interested users should contact the lead principal investigators of these cohorts (which are separate from the PGC).

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistical parameters

When statistical analyses are reported, confirm that the following items are present in the relevant location (e.g. figure legend, table legend, main text, or Methods section).

n/a	Confirmed	
☐	☒	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☐	☒	An indication of whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☐	☒	A description of all covariates tested
☐	☒	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒	A full description of the statistics including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☐	☒	For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☐	☒	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated
☐	☒	Clearly defined error bars *State explicitly what error bars represent (e.g. SD, SE, CI)*

Our web collection on statistics for biologists may be useful.

Software and code

Policy information about availability of computer code

Data collection	This is fully described in the Online Methods and associated Supplemental Tables
Data analysis	Software used is described in the Online Methods.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers upon request. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

See the last two paragraphs in the Online Methods and Table S14.

Field-specific reporting

Please select the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Glia Accumulate Evidence that Actions Are Futile and Suppress Unsuccessful Behavior

Graphical Abstract

Highlights

- Zebrafish "give up" after swim attempts repeatedly fail to generate movement
- Whole-brain imaging reveals noradrenergic neurons that encode swim failures
- Radial astrocytes accumulate the noradrenergic failure signal and trigger passivity
- Glia accumulate evidence that actions are futile, then switch behavioral state

In Brief

Whole-brain imaging in virtual-reality-immersed zebrafish reveals that failed swim attempts are detected by noradrenergic neurons, which drive glial cells that accumulate calcium until they trigger the suppression of further futile attempts.

SUMMARY

When a behavior repeatedly fails to achieve its goal, animals often give up and become passive, which can be strategic for preserving energy or regrouping between attempts. It is unknown how the brain identifies behavioral failures and mediates this behavioral-state switch. In larval zebrafish swimming in virtual reality, visual feedback can be withheld so that swim attempts fail to trigger expected visual flow. After tens of seconds of such motor futility, animals became passive for similar durations. Whole-brain calcium imaging revealed noradrenergic neurons that responded specifically to failed swim attempts and radial astrocytes whose calcium levels accumulated with increasing numbers of failed attempts. Using cell ablation and optogenetic or chemogenetic activation, we found that noradrenergic neurons progressively activated brainstem radial astrocytes, which then suppressed swimming. Thus, radial astrocytes perform a computation critical for behavior: they accumulate evidence that current actions are ineffective and consequently drive changes in behavioral states.

INTRODUCTION

Perseverance can lead to success, but some challenges are best met by high-activity bursts separated by behavioral quiescence. This pattern is often seen in motile animals that find themselves unable to move. Captured prey may become passive while waiting for a predator to loosen its grip before trying hard to escape; a fish stuck in mud may conserve energy between vigorous attempts to free itself. Periods of passivity are also observed during laboratory tasks in which an animal's actions fail to overcome challenges (e.g., passive coping, learned helplessness) (Andalman et al., 2019; Maier, 1984; Warden et al., 2012) or fail to acquire rewards (Salamone et al., 2016). Here, we studied the mechanisms of a form of "futility-induced passivity" in zebrafish to ask: how does the brain detect failures, accumulate evidence over time to infer that its motor patterns (attempts) are futile, and switch behavioral strategy?

To search for neurons involved in behavioral-state switching, we used whole-brain light-sheet imaging to survey single-cell dynamics during behavior in larval zebrafish. Because astrocytes influence neuronal activity (Bazargani and Attwell, 2016; Nedergaard, 1994; Parpura et al., 1994), we also imaged a glial cell type in zebrafish we refer to as radial astrocytes (a cell type previously also referred to in zebrafish as radial astroglia, astroglia, radial glia) (Cuoghi and Mola, 2009; Grupp et al., 2010). These cells have an apical-basal projection and bushy processes, similar to mammalian radial glia and astrocytes, respectively (Lyons and Talbot, 2014).

Interactions between astrocytes and neurons have been investigated extensively. Astrocytes can respond to neuronal activity by intracellular calcium increase. They can, in turn, influence other neurons through multiple mechanisms (Bazargani and Attwell, 2016), such as transmitter release (Araque et al., 2014) or modulation of extracellular potassium concentration (Haydon and Nedergaard, 2014; Wang et al., 2015). They play a role in controlling the states of neural networks, perform spatial and temporal integration, and can underlie slow shifts in brain states (Araque et al., 2014) like sleep and seizures (Kjaerby et al., 2017; Verdugo et al., 2019). Calcium signals in astrocytes are triggered by sensory input and behavior (Bekar et al., 2008; Ma et al., 2016; Paukert et al., 2014; Schummers et al., 2008; Srinivasan et al., 2015; Verkhratsky et al., 1998). Astrocytes can modulate circuit function and behavior (Cui et al., 2018; Gourine et al., 2010; Morquette et al., 2015; Yu et al., 2018). They can enhance memories (Adamsky et al., 2018), integrate neuronal signals over time (Deemyad et al., 2018), respond to neuromodulators including norepinephrine (NE) (Bekar et al., 2008; Ma et al., 2016; Paukert et al., 2014; Srinivasan et al., 2015; Verkhratsky et al., 1998), and serve as intermediaries between neuromodulators and neurons (Ma et al., 2016; Pabst et al., 2016). These findings raise the possibility that astrocytes play further roles typically ascribed to neurons, such as driving rapid behavioral-state switches.

To investigate brain-wide neuronal and astrocytic activity during futility-induced passivity, we used a virtual-reality (VR) environment to first simulate realistic visual feedback during attempted swimming; we then suddenly withheld this feedback to

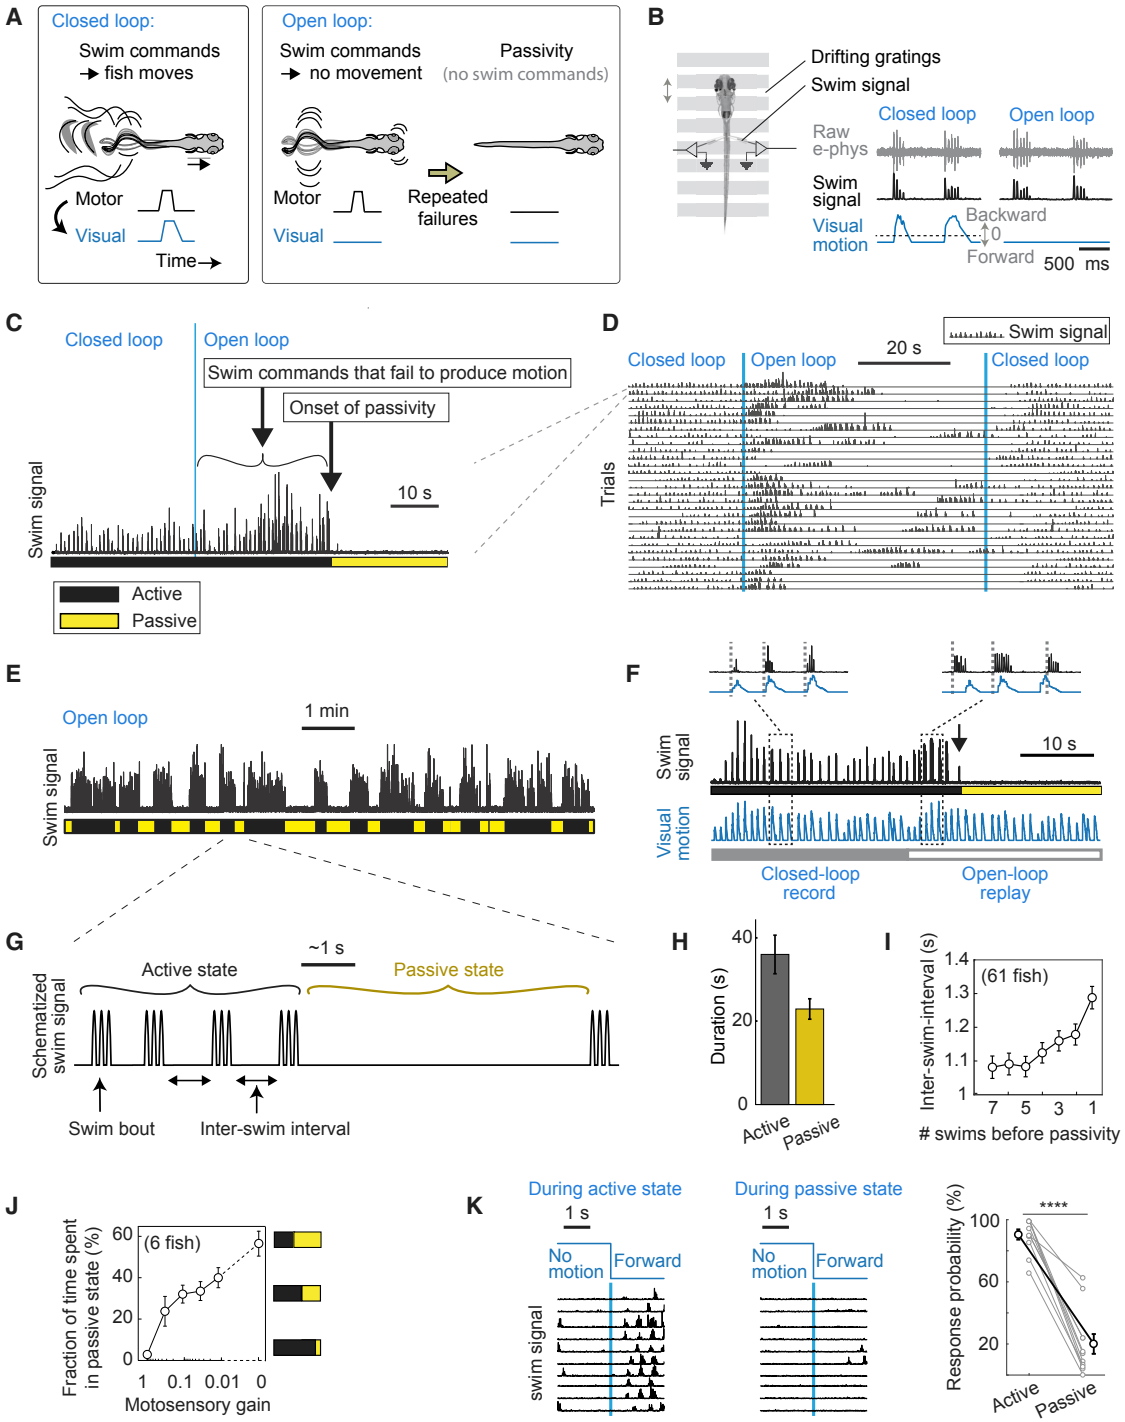

Figure 1. Lack of Visual Feedback during Swimming Triggers Passive Behavioral State

Figure360▷ For a Figure360 author presentation of this figure, see https://doi.org/10.1016/j.cell.2019.05.050.

(A) Locomotion in closed loop versus open loop. After repeated swim failures, zebrafish entered a passive behavioral state.

(B) Virtual environment for fictively swimming paralyzed fish. Unless indicated otherwise, all VR experiments used a constant forward-drifting grating to induce motor behavior. In closed loop, the visual scene was accelerated backward as fish attempted to swim; swim commands were detected from motor neuron axons with tail-attached electrodes. In open loop, the visual scene did not respond to swim commands. Dashed line, stationary grating; above dashed line, backward motion; Below, forward motion.

(C) Futility-induced passivity. In closed loop, fish swam naturalistically, at about one bout per second. In open loop, fish first swam with higher vigor, then stopped swimming for several to tens of seconds.

(legend continued on next page)

Please cite this article in press as: Mu et al., Glia Accumulate Evidence that Actions Are Futile and Suppress Unsuccessful Behavior, Cell (2019), https://doi.org/10.1016/j.cell.2019.05.050

render swim efforts ineffective. The animals responded by first increasing their motor vigor, then suddenly stopping swimming, followed by cycling between passive and vigorously active behavioral states. To mediate such behavior, the brain must detect movement failures (when a motor command does not lead to perceived motion), integrate the failure signal over multiple attempts (to infer that the attempts are futile), and switch to another behavioral strategy. Using whole-brain imaging and targeted perturbations, we found that the noradrenergic (NE) system represents sensory-motor mismatch during movement failures, that radial astrocytes accumulate these NE mismatch signals, and that resulting surges in astrocytic activity activate downstream neurons and trigger behavioral passivity. These results show that radial astrocytes are fundamental to the rapid regulation of behavioral states.

RESULTS

Withholding Visual Feedback during Swimming Induces Passivity

Since swimming is central to fish behavior, we focused on the animal's response when it perceives that swimming is futile. We created this perception by withholding the visual feedback that normally accompanies motor output in a fictive swimming VR environment. After repeatedly attempting to swim with no change in visual flow, animals became passive (Figure 1A).

Animals (5–7 days post fertilization) were placed in a virtual environment where they fictively swam in response to forward-drifting visual scenes, as if against a water current, during which they attempted to stay in the approximate same spatial location (Orger et al., 2000; Rock and Smith, 1986; Vladimirov et al., 2014). In this "closed-loop" environment (Figure 1B), swim commands, measured from motor neuron firing in the tail, triggered backward visual flow like that seen during swim bouts. This elicited naturalistic swimming at a regular rate of about one swim bout per second (Dunn et al., 2016; Kawashima et al., 2016). The fish closely followed the visual stimulus, adjusting their swim vigor to compensate for changes in motosensory gain (i.e., coupling efficiency between swimming and visual feedback) (Ahrens et al., 2012; Portugues and Engert, 2011).

Fish were then switched to an "open-loop" protocol where forward visual flow was seen but swimming did not elicit visual feedback (Figures 1A and 1B). The animals increased swim vigor for many swim bouts but then abruptly became passive for a long time (Figures 1C and 1D), after which they resumed swimming, cycling between passive and active behavioral states lasting several to tens of seconds (Figure 1E). The animals also switched to a passive state when viewing replayed visual motion patterns in open loop that had been previously recorded during closed loop (Figure 1F), indicating that the passivity resulted from decoupling sensory feedback and behavior. Passive states (epochs when the animal did not swim for at least 5 s; Figures S1A and S1B) lasted 24.4 ± 2.5 s (mean ± SEM), and active states lasted 36.1 ± 4.2 s (n = 74; Figure 1H).

Several seconds prior to passivity, fish swam more vigorously and less frequently and attempted to make larger amplitude turns (Figures 1I and S1C). They were also passive when there was some, but very little, visual feedback (very low motosensory gain; Figure 1J).

Passivity was not due to fatigue, as similar swim vigor was accompanied by different passivity durations in the lowest gain range (Figures S1E and S1F). Nor was passivity due to struggles, as most passive periods were not preceded by struggling (Figures S1G–S1I). Thus, the crucial driver of the switch to passive behavior is the absence of visual feedback during swimming.

During passivity, fish were almost non-responsive to moving visual stimuli (Figures 1K and S1J), yet neuronal activity increased in the abducens nucleus, which controls eye movements (Figure S1K), suggesting that fish attempted to move their eyes more during this time.

The alternation of two opposing behavioral states allowed us to study the mechanisms of brain-state transitions.

Correlates of Passivity in Neuronal and Astrocytic Activity

We hypothesized that the passive state might be triggered by increased activity in cells that suppress swimming. We performed whole-brain cell-resolution calcium imaging in neurons and radial astrocytes during futility-induced passivity (Figure 2A). We used a light-sheet microscope (Ahrens et al., 2013; Panier et al., 2013; Vladimirov et al., 2014) with the VR environment to image animals expressing either GCaMP6f (Chen et al., 2013) or jRGECO1b (Dana et al., 2016) in almost all neurons under the *elavl3* promoter (Park et al., 2000) or in radial astrocytes under the *gfap* promoter (Bernardos and Raymond, 2006). We imaged either cell type or both with simultaneous dual-color imaging (STAR Methods).

When animals switched from the active to the passive behavioral state, whole-brain average neuronal activity decreased,

(D) Multiple trials of futility-induced passivity from a typical fish, showing passivity and switches to active behavior. Trials are successive epochs from a continuous recording, aligned by the onset of open loop.

(E) In prolonged open loop (tens of minutes), fish cycled between active and passive behavioral states.

(F) Futility-induced passivity also occurred when the stimulus seen in closed loop was replayed in open loop, showing that passivity was not caused by a change in the pattern of the visual motion. Dashed vertical lines indicate alignment of motor and sensory events on left and misalignment on right.

(G) Diagram with terminology for behavioral transitions.

(H) Mean duration (time between behavioral transitions) of active and passive epochs in prolonged open loop, n = 74 fish. An epoch is passive if the fish did not swim for 5 s or more (see Figures S1A and S1B). Error bars, SEM in all figures.

(I) Before the switch to passivity, inter-swim interval progressively increased, n = 61 fish (see Figure S1E).

(J) Prevalence of the passive behavioral state depended on the motosensory gain (coupling efficiency between swimming and visual feedback). Naturalistic gain (≈1) induced an active state. As the gain approached 0 (i.e., open loop), fish gradually spent more and more time in the passive state. n = 6 fish.

(K) Passive fish were less responsive to visual stimuli. Active or passive states were elicited via closed loop or open loop. Then a brief static stimulus was followed by brief forward motion. In passive fish, response to motion was reduced. Left: example. Right: population data. Two-tailed paired t test, $p = 4.2 \times 10^{-7}$, n = 11 fish (see Figure S1J).

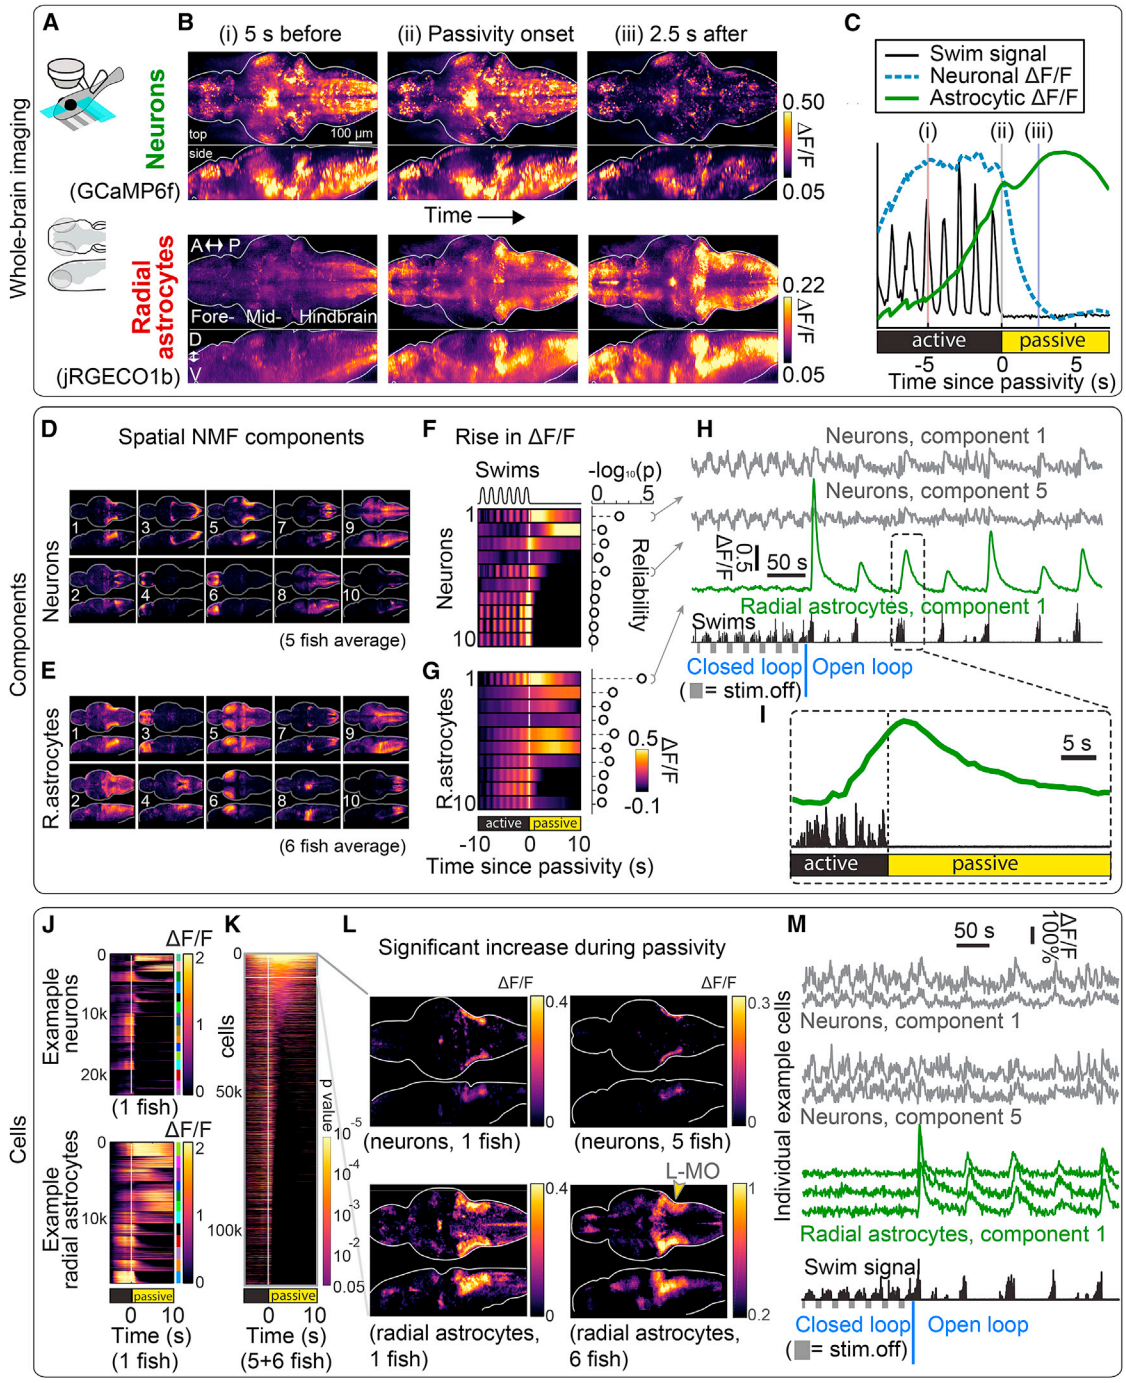

Figure 2. Whole-Brain Neuronal and Astrocyte Dynamics Show Ca^{2+} Increases in Specific Cell Populations during Futility-Induced Passivity

Figure360▷ For a Figure360 author presentation of this figure, see https://doi.org/10.1016/j.cell.2019.05.050.

(A) Experimental setup. A light-sheet microscope recorded from most radial astrocytes and neurons in the brain at cellular resolution, using either single-population GCaMP6f or simultaneous dual-color GCaMP6f and jRGECO1b recordings, while fictive behavior was monitored and visual stimulus was delivered.

(B) Whole-brain neuronal and glial activity before, at, and after passivity onset in an example *Tg(gfap:jRGECO1b); Tg(elavl3:GCaMP6f)* fish. Top: mean neuronal brain-wide activity was higher during active behavior than passivity. Bottom: conversely, mean brain-wide glial Ca^{2+} signals increased before passivity onset and remained elevated during passivity. A, anterior; P, posterior; D, dorsal; V, ventral. Images are maximum-intensity projections of means triggered on passivity onset (64 events).

(C) Neuronal and glial signals near passivity onset, averaged across the brain of the same fish from (B). Average neuronal Ca^{2+} decayed after passivity onset, while average glial Ca^{2+} increased before passivity onset and peaked soon after.

(legend continued on next page)

while glial activity increased (Figure 2B; Video S1). This increase in glial Ca^{2+} started seconds before passivity onset (Figures 2B and 2C). Both neuronal and glial Ca^{2+}, averaged across the brain, were higher and fluctuated more strongly in open loop than in closed loop (Figure S2A). Fluctuations in glial Ca^{2+} appeared strongest and most widespread during the first several switches to passivity in the minutes following the start of open loop, then became weaker and more localized.

To quantify these activity patterns in more detail and identify cell populations with similar activity patterns, we used non-negative matrix factorization (NMF) in neurons and radial astrocytes separately. A first round of NMF extracted single neurons, radial astrocytes, and segments of processes based on co-fluctuating activity of neighboring voxels (called "cell segments," or "cells" for brevity; STAR Methods). A second round factorized the brain into spatial components—sets of cells with coordinated activity (Figures 2D and 2E; Video S2)—and temporal components that describe the activity patterns of these cell groups (Figures 2F and 2G). We clustered the components into a set that occurred consistently across all fish (STAR Methods). Multiple components showed activity increases near the onset of passivity, including neuronal and glial components with elevated activity in the passive period (Figures 2F and 2G). A response reliability measure ($-\log_{10}$ p; STAR Methods) that quantifies consistency over repeated behavioral switches identified a consistent subset of glial signals (Figure 2G, component 1). Calcium in astrocyte component 1 increased before and peaked after passivity onset (Figures 2G–2I). When fish in a closed-loop protocol stopped swimming because the stimulus stopped moving, glial Ca^{2+} signals were weaker than during futility-induced passivity (Figure 2H). The most consistent surge in glial Ca^{2+} occurred in a neuropil-rich area in the lateral hindbrain, which we call area L-MO (lateral medulla oblongata, spanning rhombomeres 2–6, the area of astrocyte component 1 in Figure 2E; also called "neuropil area 4" in the Z-Brain atlas [Randlett et al., 2015] and regions #12 and #171 in Zebrafish Brain Browser [Marquart et al., 2015]).

Finally, we analyzed single-cell segments. Ca^{2+} signals from neurons and glia were analyzed near passivity onset (Figure 2J). For each cell, we used a p value to quantify the consistency of Ca^{2+} increases above baseline (Figure 2K; Video S3; STAR Methods). Of all brain regions, L-MO radial astrocytes showed the most consistent increases in activity during passivity (Figure 2L) and showed ramping Ca^{2+} signals before passivity onset (Figures 2G, 2I, 2M, and S2C–S2E). Similar glial Ca^{2+} activity occurred in another futility-induced passivity assay, where untethered fish become passive after being submerged in a viscous agarose solution (Figure S2F; Video S4).

Astrocytic Ca^{2+} started to increase before the switch to passivity (Figures 2G, 2I, and S2C–S2E). This Ca^{2+} elevation and the peak that followed at passivity onset led us to hypothesize that radial astrocytes may suppress swimming.

Anatomy of Radial Astrocytes

To provide anatomical context for these observations, we examined the morphology of radial astrocytes extending processes to the L-MO. In fish expressing GCaMP6f in radial astrocytes, some residual GCaMP6f may remain in newly differentiated neurons (Anthony et al., 2004; Fujita et al., 2014; Sloan and Barres, 2014). We examined protein expression driven by *gfap* and *elavl3* promoters and found them well segregated across the brain (Figures S3A and S3B), suggesting, together with the differences in Ca^{2+} activity (Figures 2F and 2G), that neuronal and glial Ca^{2+} measurements were well separated.

In *gfap* transgenics (Figures 3A–3C), we filled single radial astrocytes with dye to visualize their morphology (Figure 3D). The cell bodies resided in the dorsal midline of the hindbrain in rhombomeres 2–6, and the bushy processes resided in L-MO; the Ca^{2+} signals locked to passivity originate in these processes (Figures 3 and S3C–S3F). These processes ramify throughout the L-MO neuropil and appose GABAergic cell bodies at the edge of the brain (Figure 3D). The GCaMP6f signal in the L-MO can spread to the cell bodies (Figure 2D, radial astrocyte components 1→2→4; Video S1) through the connecting processes. Activation of other brain areas (e.g., glial components 3, 5, 6) happened more often right after transitions from a closed-loop to an open-loop protocol. Radial astrocytes lacked active membrane properties and had a more negative resting-membrane potential than neurons (Figure S3G), consistent with previous observations of these cells (Li et al., 2015).

(D and E) Spatial NMF components. Neuronal and glial data recorded with GCaMP6f in separate transgenic lines. Brightness: spatial NMF weights. n = 5 fish (neurons), n = 6 fish (radial astrocytes).

(F and G) Temporal neuronal and glial Ca^{2+} signals, per NMF component of (D) and (E), averaged over fish and trials, centered on passivity onset. Right: reliability ($-\log_{10}$(p)), calculated by comparing Ca^{2+} activity 1–4 s after passivity onset to mean activity 10–5 s before passivity onset (higher reliability: more consistent responses over trials). Multiple neuronal and glial components had strong correlations to behavior. Neuronal and glial component 1 overlaps with L-MO.

(H) Signals from example fish; see also Figure S2B. Fish was first in closed loop, presented with alternating moving and stationary gratings (fish swam little during stationary gratings), and next in open loop, wherein animals cycled through active and passive states. Radial astrocytes were engaged in switches to passivity in open loop, not swim pauses in closed loop.

(I) Astrocytic signal from (H), showing a rise before and peak after passivity onset.

(J) Cellular signals from segmented neurons and glia from two example fish, grouped by component (colored bars, right), relative to passivity onset.

(K) Neurons and glia (random subset) from all fish with elevated signals after passivity onset, ordered by p value from a statistical test of how reliably Ca^{2+} is increased above baseline (10–5 s before passivity).

(L) Brain maps of neurons and radial astrocytes with reliably elevated Ca^{2+} just after passivity onset (1–4 s) relative to baseline. L-MO signals were most consistently above baseline across fish. Left: example. Right: population average (5 fish for neurons, 6 for glia, registered to standard brain). p values were not used to test statistical significance but to create an exploratory functional brain map (STAR Methods).

(M) Ca^{2+} traces from single cells, same fish as in (H) and (I), during closed loop (left) and open loop (right). Radial astrocytes selectively respond to futility-induced passivity.

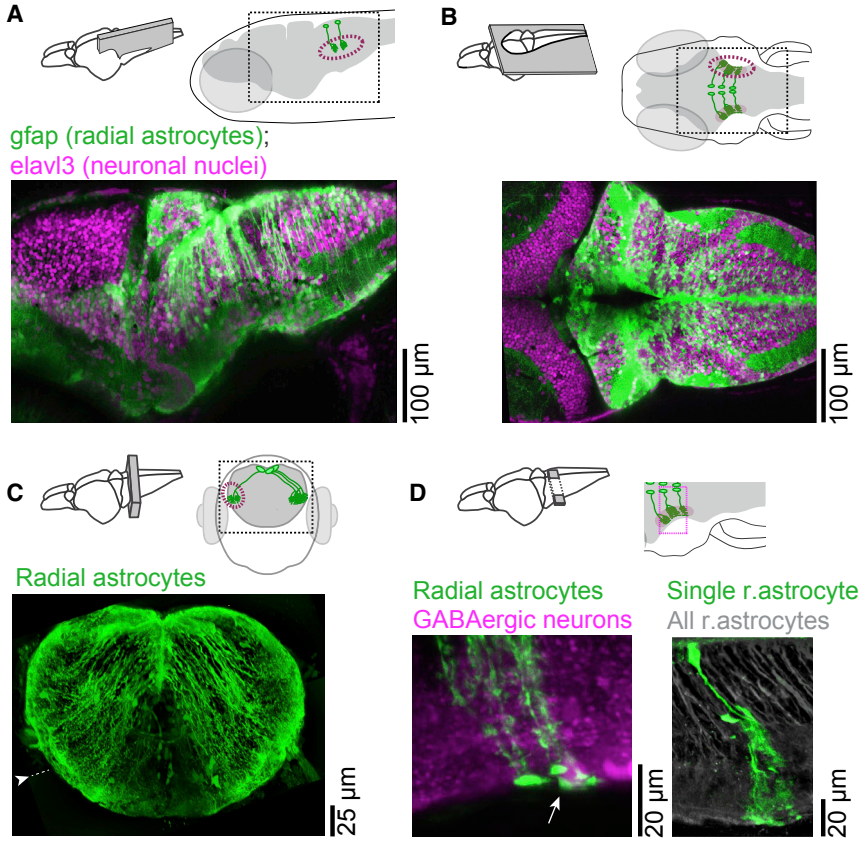

Figure 3. Morphology of Radial Astrocytes Projecting to L-MO

(A) Maximum intensity projection (MIP) along the medial-lateral axis of a 20 μm section from *Tg(elavl3:H2B-GCaMP6f);Tg(gfap:tdTomato)* fish. Dashed line, L-MO location. Neurons, magenta; glia, green.

(B) MIP along dorsal-ventral axis of a 20 μm section, same fish as (A). Radial astrocytes ramify in L-MO.

(C) MIP along the rostral-caudal axis of a 20 μm section in hindbrain. Radial astrocyte processes project ventral-laterally. Scale bar is corrected for 4× expansion (Freifeld et al., 2017; Tillberg et al., 2016) to approximate *in vivo* dimensions. Arrowhead indicates microscopy software stitching artifact.

(D) MIP along dorsal-ventral axis. Diagonal section with one (right) or several (left) radial astrocytes electroporated with synthetic dye. Astrocytic somata are proximal to dorsal midline of hindbrain; their processes run ventral-laterally, are dense in lateral hindbrain (green at brain border), and appose GABAergic somata (left: white arrow, magenta, labeled by *Tg(gad1b:RFP)*); radial astrocytes (right: gray) labeled by *Tg(gfap:jRGECO1b)*.

Radial Astrocyte Activation Increases Passivity; Silencing Decreases Passivity

Since radial astrocytes were activated before and at the transition from active to passive states, we asked whether disabling these cells prevents the behavioral-state transition and whether activating them triggers it. We used two-photon laser ablation to kill glial cells projecting to L-MO (Vladimirov et al., 2018) (~300 of ~1,000 such cells, using nuclear-localized GCaMP6f under the *gfap* promoter to target somata; STAR Methods) (Figure 4A) and assayed for futility-induced passivity. Ablated animals spent half as much time in the passive state as they did before ablation (Figures 4B and 4C), suggesting that radial astrocytes are necessary to trigger passivity. We confirmed that this effect was not restricted to fictive swimming: when deprived of visual feedback during tail motion, nonparalyzed head-embedded fish were more active after ablation (Figures 4D and S4A–S4C). This behavioral change was specific to radial astrocyte ablation, since ablation of either a matched number of neurons in random locations or a large part of the forebrain (STAR Methods) did not affect futility-induced passivity (Figures 4E, S4D, and S4E). This effect was not due to hyperactivity, since fish with glial ablation can still stop swimming and perform motor adaptation (Figures S4F and S4G). An additional nitroreductase-based chemogenetic approach to render radial astrocytes unhealthy (Tabor et al., 2014) also reduced passivity (Figure S4H). Thus, futility-induced passivity depends on the presence of healthy, functioning radial astrocytes.

Since astrocytes support neuron health (Banker, 1980; Lyons and Talbot, 2014), we controlled for adverse effects of glial ablation on neurons. After ablations, we observed no significant difference in swim frequency, power, or velocity in freely swimming fish (Figure 4F). Also, neural activity in L-MO was similar before and after glial ablation during closed-loop fictive swimming (Figure 4G), suggesting that the targeted ablation minimally affects neural activity outside of futility-induced passivity.

Finally, we blocked the inositol 1,4,5-trisphosphate receptor (IP_3R) to reduce Ca^{2+} release from intracellular stores in radial astrocytes. Ca^{2+} transients dropped (Figure S4I) when we locally puffed the IP_3R inhibitor xestospongin C (XeC) onto astrocytic cell bodies in the dorsal midline of the hindbrain (Figure 4H). We minimized exposure of neurons to XeC by injecting into a region containing mostly glia. This inactivation method also reduced futility-induced passivity (Figure 4H).

Together, these results strongly suggest that radial astrocytes are necessary for futility-induced passivity.

To test whether surges in astrocytic Ca^{2+} are sufficient to reduce swimming, we used a chemogenetic approach to increase intracellular Ca^{2+} in glia. We transiently expressed rat TRPV1 in a sparse subset (~1%) of radial astrocytes (Figure S5A; STAR Methods), rendering their membranes highly permeable to Ca^{2+} upon exposure to the agonist, capsaicin (other cells were unaffected since, unlike rat TRPV1, the zebrafish ortholog is insensitive to capsaicin) (Chen et al., 2016; Munns et al., 2015). We targeted only a tiny subset of cells to mitigate any unphysiological effects of TRPV1 activation. Application of capsaicin (5 μM) caused increased Ca^{2+} fluctuations in the population (Video S5), potentially through gap junctions (Fujii et al., 2017). The fish became passive more than 60% of the time, starting

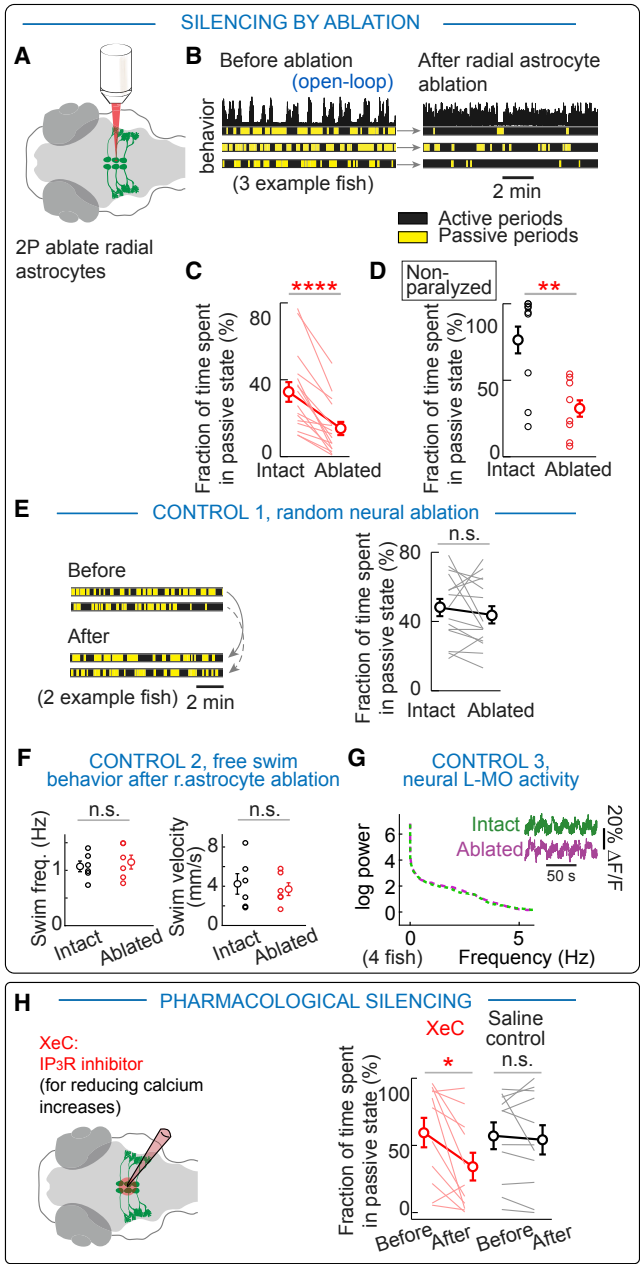

Figure 4. Radial Astrocytes Are Necessary for Futility-Induced Passivity

(A) Experimental design. ~300 astrocytes projecting to L-MO were ablated with a 2-photon laser with single-cell resolution, in fish with radial astrocytic nuclei fluorescently labeled. In all following panels, n.s., not significant; *p < 0.05; **p < 0.01; ***p < 0.001; ****p < 0.0001.

(B) Reduced futility-induced passivity after glial ablation in 3 example fish.

(C) Population data showing a ~50% reduction in futility-induced passivity. Two-tailed paired t test, $p = 1.3 \times 10^{-5}$, n = 16.

(D) Alternative assay for futility-induced passivity: unparalyzed, head-restrained tail-free also show passivity. Fish with ablated astrocytes remained active most of the time (Figures S4A–S4C). Two-tailed non-paired t test, p = 0.0041, n = 8 fish in both conditions.

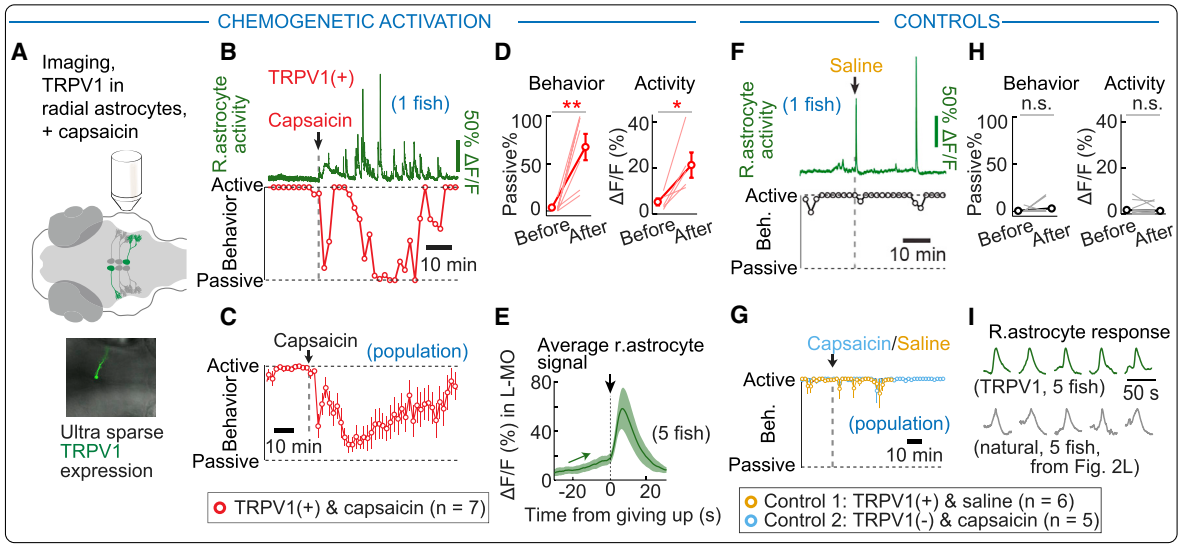
(E) Ablation of ~300 random neurons had no significant effect on passivity. Two-tailed paired t test, p = 0.34, n = 15 fish.

(F) Control for nonspecific effects of astrocytic ablation. During free swimming, ablated fish showed no abnormalities in swim frequency or velocity. Two-tailed non-paired t test, p = 0.75 for swim frequency, p = 0.67 for swim velocity, n = 6 fish.

(G) Imaging in L-MO before and after glia ablation showed no difference in neural activity in closed loop with alternating moving and stationary gratings. Inset, example activity; main panel, power spectral density. n = 4 fish.

(H) Reducing glial Ca^{2+} by blocking IP_3R reduced futility-induced passivity. XeC (100 μM inside pipette) or saline was puffed onto astrocytic somata. Two-tailed paired t test, p = 0.033, p = 0.54, n = 11 fish in both conditions.

when surges in astrocytic Ca^{2+} appeared (Figures 5A–5D) in a closed-loop environment with drifting gratings (where the normal passive time is 2.3% ± 1.2%). L-MO glial Ca^{2+} rose before passivity and peaked shortly thereafter (Figure 5E). This effect was absent when capsaicin was applied to fish without TRPV1 or saline to fish with TRPV1 (Figures 5F–5H). The temporal dynamics of capsaicin-triggered glial Ca^{2+} increases at passivity onset resembled those triggered by open loop in TRPV1-negative fish (Figure 5I), suggesting that TRPV1 evokes a naturalistic process. Unlike the switch to passivity induced by open loop, capsaicin-induced switching was not preceded by increased swim vigor (Figure S5B). Thus, surges in Ca^{2+} in L-MO radial astrocytes alone appear sufficient to stop swimming.



To test with temporal precision whether activating radial astrocytes suppresses swimming, we expressed CoChR (Klapoetke et al., 2014), a large-current channelrhodopsin, in radial astrocytes and activated it by shining blue light on L-MO with a digital micromirror device (DMD) (Zhu et al., 2012a). The resulting increase in glial Ca^{2+} (Figures 5J and S5C; Video S5) looked natural, including in its wave-like propagation (Figure S5C). However, opening this channel might elicit concomitant changes in intracellular sodium levels and pH, and although we did not detect double-labeled cells, neurons may express residual low levels of CoChR (Anthony et al., 2004; Fujita et al., 2014; Sloan and Barres, 2014). Hence, in another experiment, we expressed the optogenetic G protein-coupled receptor (GPCR) Opto-α1-AR (Airan et al., 2009) in radial astrocytes to mimic the Gq-coupled human α_{1a}-adrenergic receptor; in this case, exposure to blue light increased glial Ca^{2+}. Even if there were residual expression in neurons, this manipulation was unlikely to drive spikes due to relatively low efficiency and the indirect relationship between GPCR signaling and spiking. Both CoChR and Opto-α1-AR (Figure 5J) activation (Figueiredo et al., 2014) induced a drop in swim power (beyond a first mild drop also in controls, perhaps as the fish sees scattered blue light) (Figures 5K–5P, S5D, and S5E).

Thus we showed, with six different gain- and loss-of-function experiments, that activation of radial astrocytes can suppress swimming (Figure 5Q; caveats and controls in Table S1) and trigger the passive behavioral state.

Radial Astrocytes Drive Activity in GABAergic Neurons that Inhibit Swimming

We reasoned that any effect of an elevation in astrocytic Ca^{2+} on behavior must occur via neurons. Neurons at the edge of L-MO are reliably activated at passivity onset (Figures 2D, neuronal component 1, and S5F), suggesting that their activity increase is due to astrocytic Ca^{2+} increases. Supporting this

(legend on next page)

idea, increasing astrocytic Ca^{2+} by either CoChR or TRPV1 activates neurons at the edge of L-MO (Figures 5R, S5G, and S5H). Optogenetic activation of these neurons, which are GABAergic with processes innervating L-MO (Figure 5R), also suppressed swimming (Figure 5S). These results provide evidence that L-MO radial astrocytes activate GABAergic neurons at the edge of L-MO and suggest that these cells in turn suppress swimming.

The Noradrenergic System Conveys Swim Failures to Radial Astrocytes

Futility-induced passivity results from multiple motor failures, which must be communicated to radial astrocytes by neurons. We hypothesized that the NE system might drive radial astrocytic Ca^{2+} signals based on known relationships of norepinephrine to behavior (Sara, 2009) and its effect on astrocytes (Bekar et al., 2008; Ding et al., 2013; Ma et al., 2016; Paukert et al., 2014; Slezak et al., 2018). We found that neurons in the locus coeruleus (LC) and the NE cluster of the medulla oblongata (NE-MO; Figures 6A and S6A) (Farrar et al., 2018; Tay et al., 2011) increased activity before switches to passivity. We imaged Ca^{2+} in NE neurons and in glia simultaneously in *Tg(th-P2A-Gal4); Tg(UAS:GCaMP6s); Tg(gfap:jRGECO1b)* fish. During futility-induced passivity, signals from NE neurons and glia were temporally coupled, with NE cell responses preceding astrocytic responses (Figures 6B and 6C; Video S6).

Radial astrocytes express multiple NE receptors (Table S2; Figure S6B), and NE axons project to L-MO (Figure S6C; Video S6), indicating that glial processes in L-MO could be driven by NE neurons.

Ablating NE-MO with a two-photon laser greatly reduced time spent in passivity, but no significant reduction resulted from ablation of the LC; ablation of the serotonergic dorsal raphe nucleus (DRN) also did not result in a significant change (Figures 6D–6F). Thus, the NE-MO, which may be homologous to NE cluster A2 in mammals (Rinaman, 2011), is necessary for futility-induced passivity.

To directly test whether NE-MO activates radial astrocytes and triggers passivity, we optogenetically activated NE-MO while imaging radial astrocytes (Figure 6G) (Zhu et al., 2012a) in fish expressing CoChR in NE cells and jRGECO1b in radial astrocytes (*Tg(dbh:KalTA4); Tg(UAS:CoChR-eGFP); Tg(gfap:jRGECO1b)*). This led to Ca^{2+} responses in glial processes in L-MO and induced passivity for ~10 s (Figures 6H and 6I). In fish with radial astrocytes ablated (as in Figures 4A–4C), activation did not lead to passivity (Figures 6I and S6E), showing that passivity resulting from artificial NE-MO activation also requires radial astrocytes.

We then identified the NE receptor that activates radial astrocytes (RNA sequencing, Table S2). After adding prazosin (α1-adrenergic receptor antagonist, 50 μM) or cyclazosin (α1B receptor antagonist, 10 μM), optogenetic activation of NE-MO no longer caused radial astrocyte activation (Figures 6J–6L). Puffing an α1 agonist elicited Ca^{2+} responses, and blocking the α2 receptor did not eliminate Ca^{2+} signals (Figures S6F and S6G). Thus, the response of L-MO radial astrocytes to NE is mediated by the α1B adrenergic receptor.

Finally, we tested whether astrocytic Ca^{2+} responses were driven solely by NE or by a combination of NE and local circuit activity like mammalian astrocytes in visual cortex (Paukert et al., 2014). We used swimming, which correlates with L-MO neural activity, as a proxy for local circuit activity (Figure 6M). Activating NE-MO during swimming caused a greater glial response than activating NE-MO without swimming (Figure 6N). Thus, radial astrocyte Ca^{2+} integrates NE and local circuit activity.

Figure 5. Activation of Radial Astrocytes Reduces Swimming

(A) Experimental design. Rat TRPV1 was expressed in ~1% of radial astrocytes in *Tg(gfap:jRGECO1b)* fish. Fish were exposed to the TRPV1 agonist capsaicin.

(B) Example fish with increased Ca^{2+} transients in L-MO and concurrent increase in passivity after capsaicin treatment. The effect diminished after ~1 h, maybe due to TRPV1 desensitization and internalization (Sanz-Salvador et al., 2012), showing that fish remain healthy, as they can swim normally. Dashed line (passive) means the fish is passive 100% of the time; dashed line (active) means it is passive 0% of the time (both measured in 2 min bins).

(C) Population data, showing increased passivity after activation of TRPV1. n = 7 fish.

(D) Population data of L-MO astrocytic Ca^{2+} increase and passivity with TRPV1 activation. Two-tailed paired t test, behavior: p = 0.0029, n = 7 fish. $\Delta F/F$: p = 0.027, n = 5 fish.

(E) Astrocytic Ca^{2+} in L-MO near passivity onset. Average signal increased just before passivity onset and peaked just after, as in futility-induced passivity (Figures 2G–2I). Shading, SEM.

(F) Control, example. No reduction of swimming or increase in astrocytic Ca^{2+} when saline was added to fish expressing TRPV1.

(G) Control, population data. No change in behavior when saline was added to fish expressing TRPV1 (n = 6 fish) or capsaicin to fish without TRPV1 (n = 5 fish).

(H) Summary of controls. Experiments as in (F) and (G) were pooled. Two-tailed paired t test, behavior: p = 0.48, n = 11 fish. $\Delta F/F$: p = 0.51, n = 7 fish.

(I) Normalized mean L-MO glial Ca^{2+} signals centered on the onset of passivity, induced by TRPV1 in closed loop (top) or by motor futility in open loop (bottom). Surges appear similar. Ca^{2+} in TRPV1+ animals did not saturate.

(J) Experimental design. Local optogenetic excitation of glial processes in fish expressing CoChR or Opto-α1-AR increases glial Ca^{2+} in L-MO (CoChR shown).

(K) Optogenetic (CoChR) excitation of L-MO glia reduced swimming for ~10 s. Blue light outside the brain caused a much milder and briefer reduction.

(L and M) Population data show reduced swimming relative to controls in fish expressing CoChR (L) or Opto-α1-AR (M) in radial astrocytes. Two-tailed paired t test, CoChR, p = 0.00012, n = 9 fish; Opto-α1-AR, p = 0.0065, n = 10 fish.

(N–P) Controls for (K)–(M) show no effect in fish without CoChR or Opto-α1-AR. Two-tailed paired t test, CoChR: p = 0.89, n = 6 fish. Opto-α1-AR, p = 0.50, n = 8 fish.

(Q) Summary of Figures 4 and 5, showing significant increases in passivity after increases in astrocytic Ca^{2+}, decreases after astrocytic silencing, and no effects in control experiments. Effects are normalized by maximal possible change (control passive % for decreases; control active % for increases) for each fish.

(R) Optogenetic activation of L-MO radial astrocytes activates GABAergic neurons at edge of L-MO in *Tg(gfap:CoChR-eGFP);Tg(elavl3:jRGECO1b)* fish. Left: maximum-intensity projection of $\Delta F/F$ after optogenetic activation of radial astrocytes (magenta) and anatomy (cyan) in example fish. Inset: Ca^{2+} in GABAergic neurons after astrocytic activation; stimulation time in cyan. Top right: *Tg(gad1b:RFP);Tg(elavl3:H2B-GCaMP6f)* used to label GABAergic neurons; bottom right: *Tg(gad1b:Gal4);Tg(UAS:CoChR-eGFP)* to sparsely label GABAergic neurons.

(S) Activation of GABAergic cells with laser light in *Tg(Gad1b:Gal4);Tg(UAS:CoChR-eGFP)* suppresses swimming. Two-tailed paired t test, p = 0.0074, n = 7 fish.

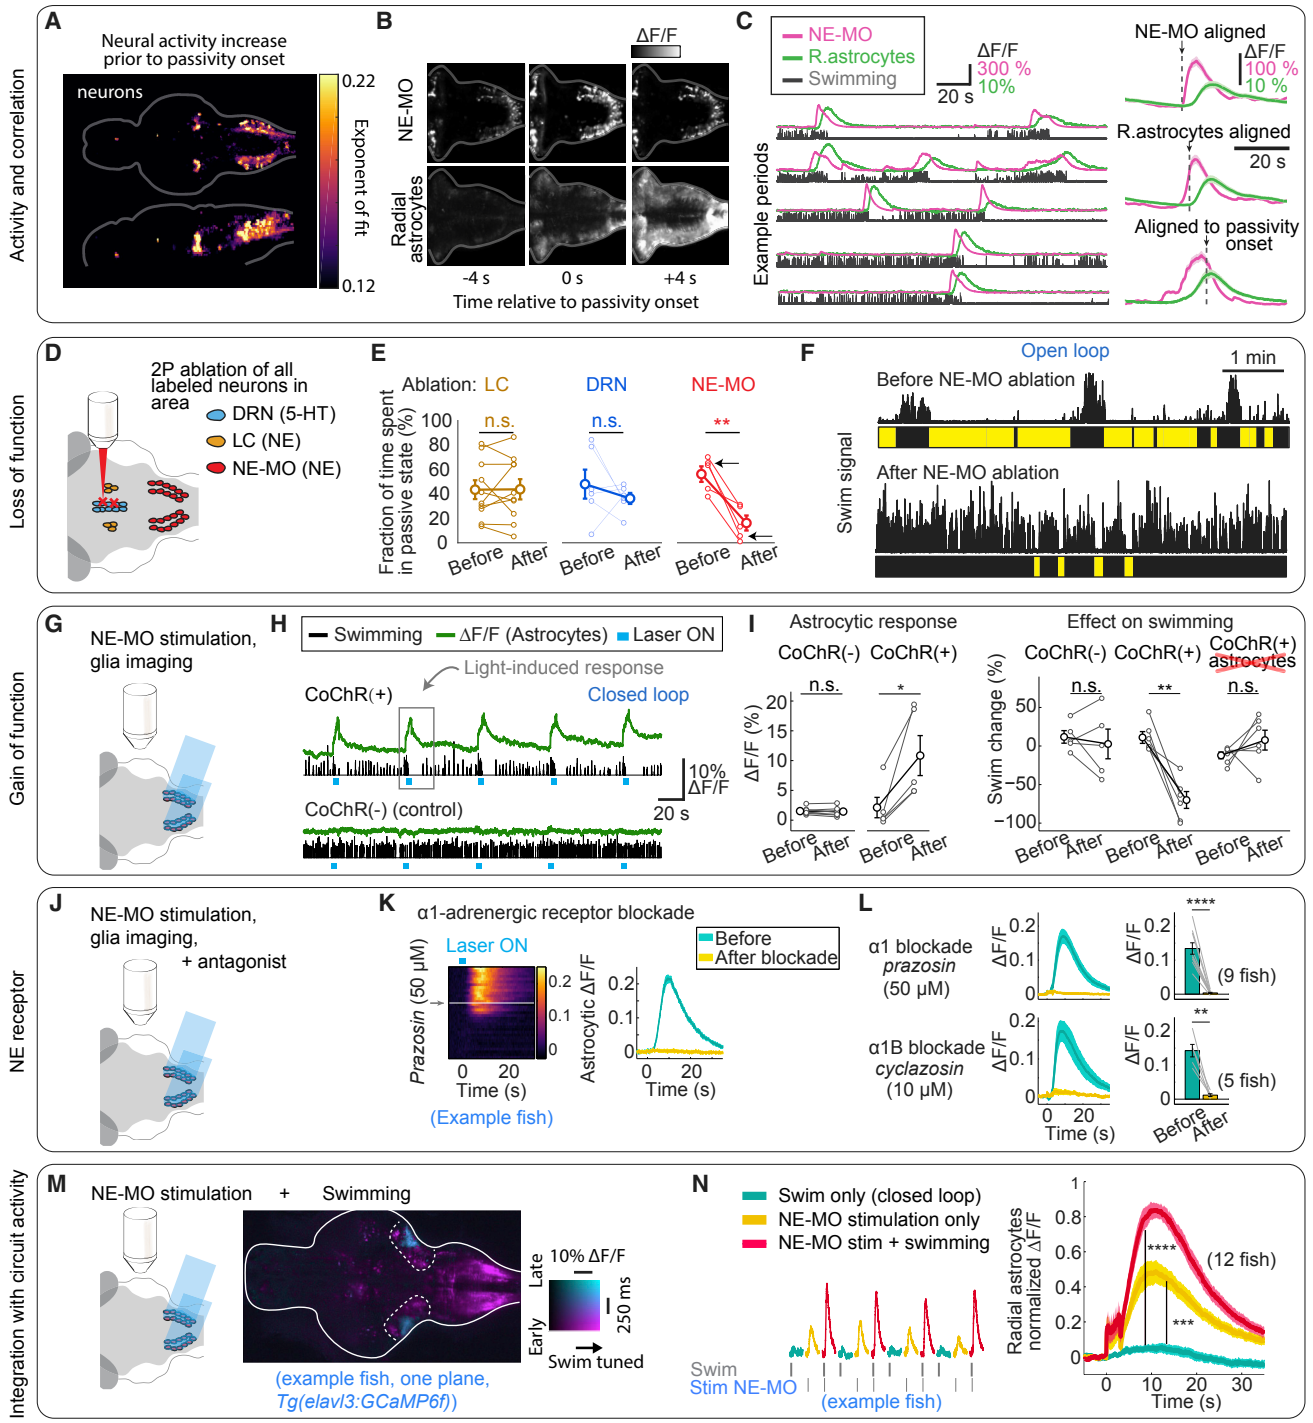

Figure 6. Noradrenergic System Activates Radial Astrocytes and Is Required for Futility-Induced Passivity

(A) Rate of neuronal activity increase before passivity onset quantified by the exponent of an exponential fit to average Ca^{2+} signals before passivity (overlay of 5 fish, *Tg(elavl3:GCaMP6f)*). Population with the highest rate of increase overlaps with NE neurons (see Figure S6A).

(B) Simultaneous imaging of NE neurons and radial astrocytes. Example Ca^{2+} signals just before, at, and after passivity onset.

(C) Examples of NE-MO activity, glial Ca^{2+} increases, and swimming in an alternating closed- and open-loop protocol. Right: average Ca^{2+} activity from NE-MO and radial astrocytes, aligned to NE-MO response onset, radial astrocyte response, or passivity onset.

(D) Experimental design: single-cell 2-photon ablation of LC, NE-MO, or DRN in transgenic zebrafish labeling these nuclei.

(E) Time in passivity was strongly reduced after NE-MO ablation, but not after ablation of LC or DRN. Two-tailed paired t test, p = 0.95, n = 10 fish for LC; p = 0.40, n = 6 fish for DRN; p = 0.0070, n = 5 fish for NE-MO.

(legend continued on next page)

What information does NE convey to radial astrocytes? If L-MO radial astrocytes encode swim futility (the time integral of failures), we hypothesized that the NE system encodes swim failures. To look for such signals, we imaged NE cells in three conditions, randomly interleaved over swim bouts: (1) fictive swimming in closed loop with backward visual flow to mimic "successful" swimming (92% of swims), (2) backward visual flow without swimming (4%), and (3) swimming in open loop without visual feedback (4%) to mimic "failed" swims (Figure 7A). If NE cells detect mismatch (Keller et al., 2012), they should be more activated in (3) than in (1) or (2). Indeed, that is what we found (Figure 7B): NE-MO responses were small or absent when fish swam with naturalistic feedback but large when they swam without feedback.

We next quantified whether NE-MO responses encode the difference between perceived and expected visual feedback during swimming. We randomized motosensory gain to elicit successful swims (gain > 0; swim generates backward visual motion) and failed swims (gain $\leq$ 0; swim with no visual change or motion opposite to expected; Figure 7C). NE-MO responses were consistent with a mismatch signal, increasing when motor vigor increased without visual effect (Figures 7D and 7E), or when vigor was constant and backward visual flow was absent or forward flow was seen (Figures 7F and 7G). Thus, NE-MO signals swim failures by encoding sensory-motor mismatch.

Radial Astrocytes Integrate Evidence that Actions Are Futile

Determining that a behavior is futile requires integrating the results of multiple successive attempts. Failed swims lead to elevated NE-MO activity, which in turn excites astrocytes (Figure 7H). NE-MO Ca^{2+} eventually leveled out or decreased (Figures 7H and 7I), while astrocytic Ca^{2+} continued to increase (Figures 7H and 7I). As radial astrocytes respond to sensory-motor mismatch signals from NE-MO and accumulate them over time, we asked whether they integrate evidence (Pinto et al., 2018; Shadlen and Newsome, 2001) that actions are futile. We designed a behavioral task in which swimming leads to visual flow probabilistically (Figure 7J). First, in closed loop, all swim bouts trigger visual flow. Next, every swim bout triggers visual flow with probability P. Glial Ca^{2+} rose fastest when P = 0 (always futile), did not rise when P = 1 (always effective), and increased at intermediate rates for intermediate P (Figure 7K). This shows that, following a switch from a closed-loop to a stochastic feedback protocol, radial astrocyte Ca^{2+} reflects evidence accumulation. Together, these results (Table S3) show mechanistically how radial astrocytes encode experience and control behavioral state.

DISCUSSION

Here, we found that the fish analog of the mammalian astrocyte is a central computational element of a circuit implementing a behavioral-state change after integrating sensory information. Specifically, radial astrocytes in a subregion of the brainstem in larval zebrafish temporally integrate noradrenergically encoded failures to accumulate evidence of futility before inducing a state of passivity ("giving up"). This behavioral pattern has a familiar combination of features: trying to achieve a goal, repeatedly failing despite trying harder, giving up temporarily, and then trying again—fish swim more vigorously in open loop (i.e., ineffective swim attempts), become passive, then swim again. Using whole-brain imaging, we found that astrocytic calcium was elevated just before—and during—passive states. Activation and silencing experiments established that these glial cells are required to trigger the passive state. Neuronal imaging and manipulation showed that the NE system encodes an expectation-outcome mismatch signal, which activates Ca^{2+} signaling in radial astrocytes. Thus, behavioral failures are detected by NE-MO and integrated by glia, which, after accumulating sufficient evidence of motor futility, trigger a passive behavioral state via GABAergic neurons. Once passivity is triggered, its persistence may be due to sustained effects of the glial cells on neurons, or a lag in the reactivation of swim circuits. These results imply that routinely including astrocytes in systems neuroscience studies may accelerate achieving a comprehensive understanding of brain function (Barres, 2008).

This study extends the known roles of glial cells to include a specific computation (temporal integration of a behaviorally relevant mismatch signal), resulting in a direct, fast effect on brain and behavioral state (induction of passivity within seconds). The traditional view of astrocytes as supporting cells for neurons is known to be incomplete (Araque et al., 2014; Kjaerby et al., 2017), as they actively influence neuronal activity.

(F) Example shows NE-MO ablation reduced futility-induced passivity. Arrows in (E), corresponding data points.

(G) Experimental design: optogenetic activation of NE-MO cells using DMD-targeted light delivery in fish expressing CoChR in NE cells while imaging radial astrocytes expressing jRGECO1b.

(H) Example fish, NE-MO activation led to increased L-MO glial Ca^{2+}, then passivity. Swimming increases briefly at light onset (see Figure S6D).

(I) Population data: NE-MO activation increased L-MO glial Ca^{2+} (left) and reduced swimming (right) in $CoChR^{+}$ fish. Two-tailed paired t test, $CoChR^{+}$ imaging, p = 0.025, n = 5 fish; $CoChR^{+}$ behavior, p = 0.0024, n = 6 fish; $CoChR^{-}$ imaging, p = 0.52, n = 7 fish; $CoChR^{-}$ behavior, p = 0.56, n = 5 fish; glial ablation, p = 0.27, n = 6 fish.

(J) Experiment to identify receptors. Experiment as in (G) with NE receptor antagonists added to bath.

(K) α1 NE receptor antagonist prazosin (50 μM) abolishes radial astrocyte response evoked by NE-MO stimulation.

(L) Population data. α1 NE receptor antagonist prazosin (50 μM) or α1B antagonist cyclazosin (10 μM) abolished radial astrocyte responses. Two-tailed paired t test, prazosin, $p = 4.6 \times 10^{-5}$, n = 9 fish; cyclazosin, p = 0.0042, n = 5 fish. Shading, SEM.

(M) Experimental design to test whether L-MO radial astrocytes integrate NE and local circuit activity. In closed loop, NE-MO cells are optogenetically stimulated during swimming (higher L-MO neuronal activity), or during not swimming.

(N) Integration of NE and local circuit activity. Radial astrocytic Ca^{2+} responses to NE during swimming are larger than to NE alone. Left: examples from successive trials. Right: summary of all fish. Two-tailed paired t test, $p = 2.4 \times 10^{-4}$ for NE-MO stimulation only versus swimming only, $p = 2.4 \times 10^{-8}$ for NE-MO stimulation + swimming versus swimming only, n = 12 fish. Shading, SEM.

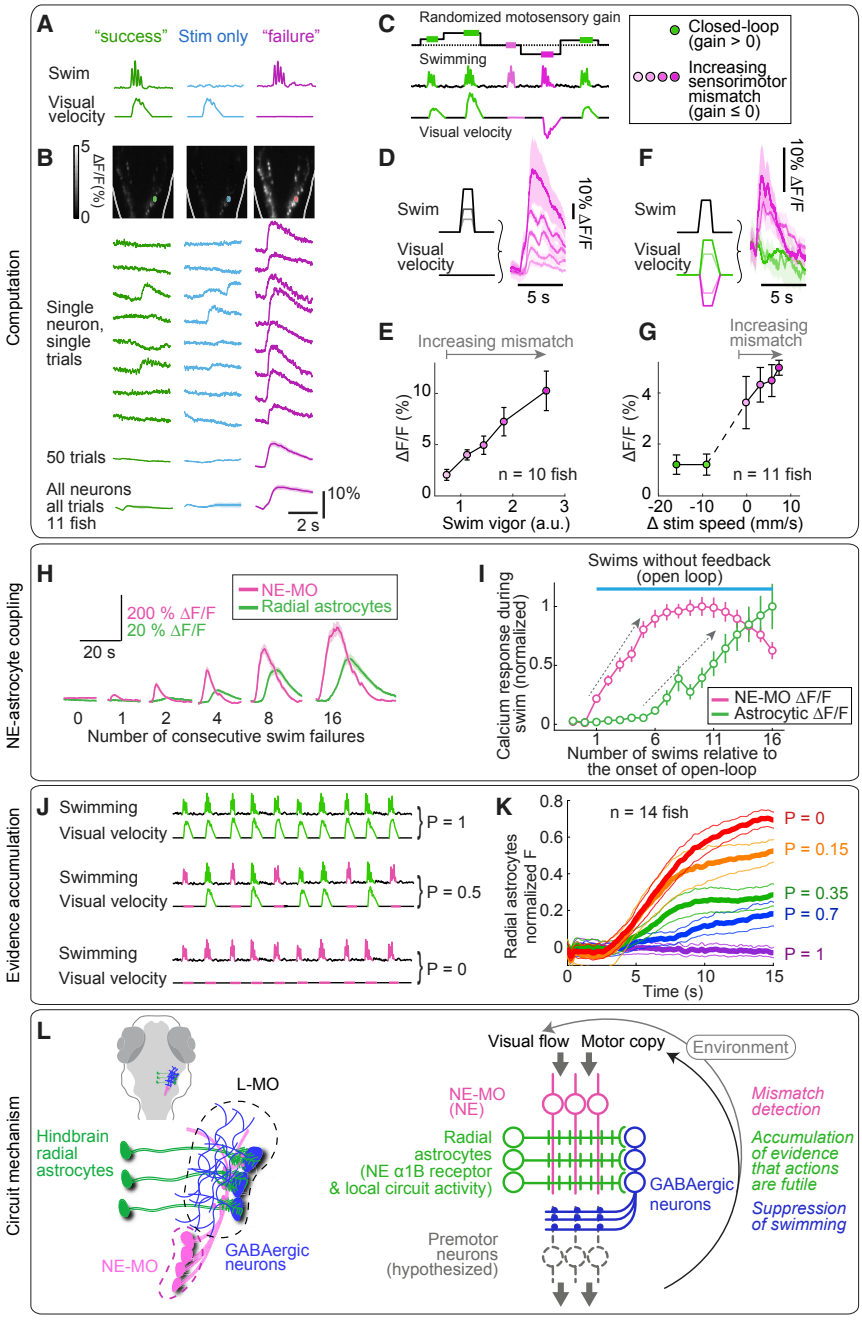

Figure 7. Noradrenergic System Signals Visuomotor Mismatch; Radial Astrocytes Accumulate Evidence that Actions Are Futile

For a Figure360 author presentation of this figure, see https://doi.org/10.1016/j.cell.2019.05.050. Figure360▷

(A) Mismatch assay. Left: in closed loop, motor output triggers visual feedback (motosensory gain > 0). Middle: stimulus only with no swimming. Right: sensory-motor mismatch in swim failures (gain = 0).

(B) Mismatch signals in NE-MO. In closed loop or visual signal alone, NE-MO responses were small. During swim failures, NE-MO responses were large. (See Figure S6H for LC, which does not respond to mismatch until next swim bout.)

(C) Extended mismatch assay: motosensory gain randomly set for each swim bout, varying combinations of motor vigor and visual velocity.

(D–G) NE-MO responses encode sensory-motor mismatch. (D and E) NE-MO responses grew with stronger motor vigor if no visual stimulus was shown. (D, example fish; E, population data, 10 fish.) (F and G) NE-MO responses were minimal in closed loop (motosensory gain > 0), whether gain was high or low. In open loop (no feedback, gain = 0) NE-MO responded. With opposite feedback (forward visual feedback during swimming, high mismatch, motosensory gain < 0), NE-MO response was larger. In (F and G), average motor vigor is similar across visual speeds due to randomization of gain. (F, example fish; G, population data, 11 fish). Shading, SEM.

(H) Radial astrocyte Ca^{2+} integrates swim failures. Fish swam in closed loop, then open loop for 1, 2, 4, 8, or 16 swim bouts, then back to closed loop. Glial signals increased with number of failed bouts after ~2 failed bouts; NE-MO signals began increasing with first failed bout. Trials with passivity not included. NE-MO signal sometimes saturated or decreased while glial Ca^{2+} continued to increase.

(I) Radial astrocyte Ca^{2+} accumulated with increasing numbers of swim failures. NE-MO Ca^{2+} also increased initially but saturated or decreased, while glial Ca^{2+} continued to increase with swim failures until feedback returns to closed loop. Gray arrows, accumulation.

(J) Experiment: information accumulation in radial astrocytes. In a swim bout, probability that fish sees visual feedback (backward visual flow) is P. P = 1, closed loop; P = 0, open loop; intermediate P gives probabilistic feedback.

(K) Information accumulation in radial astrocytes. Ca^{2+} signal, averaged over fish and trials, reflects P, the probability that a swim bout gives visual feedback, so glia accumulate information on swim futility over time (n = 14 fish).

(L) Circuit diagram. NE-MO represents mismatch signal, computed from visual and motor efference input. Noradrenergic axons from NE-MO excite glial processes in L-MO through α1B NE receptors (see Figure S6C for projections). Radial astrocytes integrate mismatch signals and suppress swimming via downstream GABAergic neurons.

In the hippocampus, astrocytes can be intermediates between cholinergic input and interneurons (Pabst et al., 2016). Glial cells in zebrafish are activated before and during generalized seizures (Verdugo et al., 2019). These and other studies (Adamsky et al., 2018; Ding et al., 2013; Paukert et al., 2014; Poskanzer and Yuste, 2016; Srinivasan et al., 2015) point to an integrated role for astrocytes in information processing in brain circuits.

Our study establishes radial astrocytes as essential computational elements in a circuit that mediates an adaptive behavioral response. The algorithm implemented by the radial astrocytes here is surprisingly analogous to that observed in mouse

hippocampal slices (Deemyad et al., 2018). There, astrocytes integrate neural signals over many seconds and then suddenly switch into a mode where they drive strong inhibition. This "integrate and suppress" functional motif may therefore generalize across neural systems and species. Interestingly, a role for astrocytes in regulating active and passive states of circuits, albeit in a mechanistically different form and on a longer timescale, was conjectured a century ago (Ramon y Cajal, 1895).

How do radial astrocytes drive activity in GABAergic edge cells? Astrocytes can influence synaptic transmission and neuronal firing in multiple ways (Bazargani and Attwell, 2016), but it is unclear which mechanisms are most relevant *in vivo* (Fiacco and McCarthy, 2018; Savtchouk and Volterra, 2018). In *Drosophila*, astrocytes inhibit downstream neurons likely through ATP secretion to influence chemotaxis and startle behavior (Ma et al., 2016). Astrocytes can release GABA (Angulo et al., 2008; Lee et al., 2010; Christensen et al., 2018). They can also influence neuronal firing by modulating extracellular ionic composition. On slow timescales, astrocytes affect neuronal firing via changes in the density of inward-rectifying K^+ membrane channels during depression in rodents (Cui et al., 2018). On faster timescales, glia-like support cells in the developing cochlea trigger neural activity in adjacent hair cells by modulating extracellular K^+ through a calcium-activated chloride channel (Wang et al., 2015). Our study shows that radial astrocytes modulate neurons and influence behavior over seconds (likely triggered by intracellular Ca^{2+} signaling, but possibly via other second messenger systems). The molecular mechanisms were not identified, but may include active control of extracellular ion concentrations near the GABAergic neurons. Radial astrocytes may affect behavior through more pathways than only the GABAergic L-MO cells. Other routes may exist between the glial cells and other neuron types, potentially including direct suppressive effects (Christensen et al., 2018; Wang et al., 2012) on premotor neurons.

Homology between radial astrocytes in zebrafish and astrocytes in mammals is suggested by several similarities. Both cell types have a bushy morphology, which in zebrafish appears after intense neurogenesis (2–3 days post fertilization [David Lyons, personal communication]), qualitatively similar to the emergence of bushy processes when mammalian radial glia convert to astrocytes at the end of embryonic development (Kriegstein and Alvarez-Buylla, 2009). We also found that fish radial astrocytes integrate norepinephrine with local circuit activity, similar to astrocytes in mammalian cortex (Paukert et al., 2014). These findings, in combination with overlapping gene expression and morphological features (Lyons and Talbot, 2014), suggest that the mechanisms shown here may be relevant for neuron-astrocyte interactions and glial control of behavior in other vertebrates.

Neuronal manipulation experiments come with caveats (Otchy et al., 2015); glial manipulation experiments come with more (see Table S1), in part because tools for manipulating glia are less established. Thus, we did six experiments to activate or silence radial astrocytes, attempting to falsify our emerging model that astrocytic activation halts swimming in futility-induced passivity. All six support a causal role for glia in triggering passivity.

Our finding that the NE system encodes the magnitude of failure is consistent with noradrenergic neurons encoding changes in relationships between actions and outcomes (Aston-Jones and Cohen, 2005; Bouret and Sara, 2004; Sara, 2009; Tervo et al., 2014). NE also encodes alertness in zebrafish (Lovett-Barron et al., 2017), which may correlate to the temporary increase in swim vigor after actions become ineffective.

Different action-outcome contingencies lead to different behaviors. When desired outcomes are attainable, motor learning fine-tunes actions; when they are unattainable, futility-induced passivity interrupts behavior. The serotonergic system mediates a form of motor learning in zebrafish by integrating backward visual flow during swimming (Kawashima et al., 2016). Thus, multiple neuromodulatory systems underlie complementary adaptive strategies: the serotonergic system encodes the degree of success of actions and leads to fine-tuning of swim vigor, while the noradrenergic system encodes failure and can drive passivity.

Futility-induced passivity belongs to a class of behaviors in which motor output is reduced, including learned helplessness (Maier, 1984), passive coping (Andalman et al., 2019; Warden et al., 2012), feigned death (Humphreys and Ruxton, 2018), and break-point behavior, where attempts to achieve reward are abandoned (Salamone et al., 2016). Although the behavior studied here is mediated by cells in the brainstem, this broader class of behaviors can involve other brain regions in mammals, including multiple neuromodulatory systems and cortical areas (Roseberry and Kreitzer, 2017).

Evidence-accumulation signals have been found in neuronal firing rates in multiple decision-making paradigms (Scott et al., 2017; Shadlen and Newsome, 2001). Here, we found that, following a switch from a closed-loop to a stochastic feedback protocol, calcium levels in radial astrocytes reflect evidence that actions are futile. The intracellular messengers in the pathway from NE receptors to intracellular Ca^{2+} increases may also be involved in the accumulation process. It remains to be elucidated which of these molecules gets thresholded (and how) to mediate the "decision" to trigger passivity.

We ascribe evidence accumulation to radial astrocytes and sensory-motor-mismatch encoding to NE-MO, but the boundary between the two operations may not be strict. NE-MO may take part in the accumulation, for example over shorter timescales or during the first few swim failures.

What class of computations might astrocytes support? In addition to having different inputs from neurons, these cell types may be specialized for different input-output transformations, based on their spatiotemporal dynamics. Neurons convert chemical inputs into membrane voltage, electrically integrate across thousands of such inputs, and fire action potentials in milliseconds. Although glial processes can respond to neurons in ~100 ms (Stobart et al., 2018), glia often operate on slower timescales using molecular signaling. Such properties may favor astrocytes for computations involving slow integration of activity. The molecular mechanisms of astrocytic computation are not yet clear, and understanding their spatial interactions with neurons may require incorporating astrocytes into electron microscopy-based circuit reconstruction (Briggman and Bock, 2012). Broadening such efforts to include astrocytes will likely accelerate neuroscience discovery.

STAR★METHODS

Detailed methods are provided in the online version of this paper and include the following:

- KEY RESOURCES TABLE
- LEAD CONTACT AND MATERIALS AVAILABILITY
- EXPERIMENTAL MODEL AND SUBJECT DETAILS
  - Zebrafish
  - Transgenesis
- METHOD DETAILS
  - Preparation for fictive-behavior assays
  - Fictive behavior in virtual reality
  - Futility-induced passivity behavioral analysis
  - DMD-based optogenetic stimulation
  - Two-photon ablation of cells
  - Forebrain lesioning
  - TRPV1-mediated activation of radial astrocytes
  - IP_3 receptor blockade
  - Analysis of fluorescence imaging data
  - Confocal microscopy
  - Single-cell radial astrocyte tracing
  - *In situ* hybridization
  - Immunohistochemistry with expansion microscopy
  - RNA sequencing
- DATA AND CODE AVAILABILITY

SUPPLEMENTAL INFORMATION

Supplemental Information can be found online at https://doi.org/10.1016/j.cell.2019.05.050.

A video abstract is available at https://doi.org/10.1016/j.cell.2019.05.050#mmc11.

ACKNOWLEDGMENTS

We thank C. Wang, P. Keller, and T. Kawashima for help with optics; A. Lemire and L. Wang for help with transcriptomics; P. Tillberg and A. Hu for help with anatomy imaging and tissue expansion; M. Copeland for help with *in situ* hybridization; M. Koyama for help with electrophysiology infrastructure; I. Bianco, H. Burgess, and D. Lyons for suggestions; M. Koyama, N. Spruston, D. Bergles, J. Du, J. Lippincott-Schwartz, J. Freeman, J. Wittenbach, D. Wolpert, J. Dudman, M. Hale, E. Yaksi, C. Brody, F. Engert, K. Monk, M. Hatten, B. Khakh, Y. Liao, and C. Zuker for discussions; V. EXPERIMENTAL MODEL AND SUBJECT DETAILS

Zebrafish

Larvae were reared at 28.5°C in 14:10 light-dark cycles (Westerfield, 2007). Zebrafish from 5 to 7 dpf were fed rotifers and used for experiments. All experiments complied with protocols approved by the Institutional Care and Use Committee at Janelia Research Campus (JRC). Zebrafish sex cannot be determined until ~3 weeks post-fertilization (Uchida et al., 2002), so experimental animals' sex was unknown.

Transgenesis

Transgenic zebrafish larvae were in *casper* or *nacre* background (White et al., 2008). *TgBAC(gad1b:loxP-RFP-loxP-GFP)* (Satou et al., 2013) was used without Cre-mediated recombination and called *Tg(gad1b:RFP)*. *Tg(elavl3:GCaMP6f)*^{jf1}, *Tg(elavl3:H2B-GCaMP6f)*^{jf7}, *Tg(elavl3:ReaChR-TagRFP-T)*^{jf10}, *Tg(elavl3:jRGECO1b)* lines are described (Chen et al., 2013; Dana et al., 2016; Dunn et al., 2016; Vladimirov et al., 2018). *Tg(gfap:jRGECO1b)*, *Tg(gfap:GCaMP6f)*, *Tg(gfap:CoChR-eGFP)*, *Tg(gfap:opto-α1AR-eYFP)*, *Tg(gfap:H2B-GCaMP6f)*, *Tg(dbh:KalTA4)*, *Tg(UAS:CoChR-eGFP)*, and *Tg(gfap:tdTomato)* lines were generated with Tol2 system (Urasaki, 2009), a known gfap promoter sequence (Bernardos and Raymond, 2006) and the following:

1. Construct containing dopamine-β-hydroxylase (dbh) promoter (dbh-GFP-pDEST-ISce); a gift from Thomas Look (Dana Faber Cancer Institute)
2. Construct containing transient receptor potential cation channel subfamily V member 1 (TRPV1) (or capsaicin receptor) from rat; a gift from David Prober (California Institute of Technology)
3. pEGFP-gfap (Intron1/5′/Exon1-zebrafish) (Addgene plasmid # 39761)
4. FCK-gene86-GFP (CoChR); a gift from Ed Boyden (Klapoetke et al., 2014)
5. pcDNA3.1-opto-α1AR-EYFP (Addgene plasmid # 20947)

Tg(gad1b:Gal4) was generated by CRISPR-mediated knock-in of Gal4 (Gal4FF) at gad1b locus as described (Kimura et al., 2014). The sgRNA sequence for gad1b is TGGAACTGCTCACCAGAAGG. 2XNRSE-tbait-hsp70-Gal4 (Kimura et al., 2014) was a gift from Shin-ichi Higashijima.

METHOD DETAILS

Preparation for fictive-behavior assays

All animals in fictive-behavior experiments were paralyzed and restrained. To induce paralysis, we bathed the fish in a 5 mg/mL solution of the nicotinic acetylcholine receptor antagonist α-bungarotoxin for 30 s, then transferred to fish facility water. Once fish no longer responded to tactile stimuli, we transferred them to a plastic Petri dish (for behavioral experiments) or a custom-fabricated sample holder (for light-sheet imaging). Paralyzed fish were then immersed in low-melting point agarose (Sigma) and oriented before it congealed.

Fictive behavior in virtual reality

For fictive swimming and virtual reality (Vladimirov et al., 2014), paralyzed zebrafish were mounted on an acrylic pedestal inside a square water-filled chamber with glass walls and a diffusive screen at the bottom for stimulus projection. Agarose was removed from the head and tail, and large-barrel glass pipettes (~60 μm inner diameter) were attached to the tail with gentle suction. The standard deviation of the left and right motor nerve signal (amplified by a MultiClamp 700B microelectrode amplifier) was calculated in a sliding window of 10 ms: this formed the 'swim signal' or 'swim power' used to quantify behavior.

In closed-loop one-dimensional environments, a stripe pattern (2.5 mm stripe width) was projected underneath the fish by a video projector (MP-CD1, Sony). This pattern moved forward at 2.86 mm/s drift speed when the fish was not swimming. When the fish

swam, the stripe accelerated backward at a rate proportional to swim power, i.e., [stimulus velocity] = [drift speed] – [motosensory gain] × [swim power]. This feedback mimics the visual feedback the animal would receive if it were freely swimming. When [swim power] = 0, forward velocity mimics the fish moving backward (as in a virtual water stream).

In open loop, the gain was zero, so the stripes moved forward at a fixed velocity, independently of whether the fish swam or not.

Brain imaging during fictive behavior used a custom light-sheet microscope, as described (Vladimirov et al., 2014). Briefly, two low-NA laser beams were scanned in the horizontal and vertical planes. The beams entered the chamber through the glass walls. One beam came from the side (relative to the head) and the other from the front of the fish and scanned the area between the eyes. The side laser was switched off at every sweep when pointing at the eye to avoid stimulating the retina. For every horizontal layer sweep, one image was acquired using a 16x/0.8 NA detection objective (Nikon), Nikon tube lens, and a camera (Orca Flash 4.0 v2, Hamamatsu). After each sweep, vertical position of the lasers and imaging objective was changed by 5 or 8 μm until a full brain volume was acquired (3 volumes/second). For GCaMP6s/f imaging, a blue laser (488 nm) was used for excitation with a green 525/50 nm detection filter (Semrock). Red light delivered visual stimulus. For jRGECO1b imaging, a green laser (561 nm) was used for excitation with a red 630/92 nm filter for detection (Semrock). For two-color imaging, 488 nm and 561 nm lasers were used simultaneously. An image splitter (W-View Gemini, Hamamatsu) separated a green and a red component (with a 525/50 nm detection filter (Semrock) for green emission and a 645/75 nm detection filter (Chroma) for red emission); red and green images were recorded on opposite halves of the same camera chip. Blue light delivered stimulus (animals showed optomotor response to either blue or red light from the video projector).

Futility-induced passivity behavioral analysis

Futility-induced passivity was defined by the inter-swim-interval. Paralyzed fish in closed loop in our VR setup typically swam in discrete bouts, about once per second (1.2 ± 0.05 s, n = 74). When switched to open loop, after swimming for ~20 s, fish paused for ~20 s in the passive state. About 50% of fish showed this behavior at 6-7 d.p.f.; fish that did not become passive in the open loop protocol were not included in subsequent analyses (50%). The active/passive state switching created a bimodal distribution of inter-swim intervals (Figure S1A), according to which we chose 5 s as the threshold defining passive epochs. An active epoch was defined as a chain of swim bouts separated by intervals under 5 s with more than 5 s between the start of the first swim bout and the end of the last bout. The two types of intervals segregated epochs well (1.19 ± 0.047 s inter-swim-interval in active epochs versus 24.4 ± 2.5 s in passive epochs, n = 74, Figure S1B). The average length of active epochs was 36.1 ± 4.2 s, and the fish swam 29 ± 6 times (n = 74) during each epoch.

DMD-based optogenetic stimulation

To target specific populations of cells for optogenetic stimulation, we built two photostimulation modules using digital micromirror devices (DMD) from commercial projector displays (P-300, AAXA; Lightcrafter discovery kit, Texas Instruments; see Optical Pathway for Optogenetic Stimulation). One photostimulation module was integrated to a standard epifluorescence microscope, and the other was integrated to our light sheet microscope. The optical design of our photostimulation modules is described (Zhu et al., 2012a). Briefly, the DMD was illuminated by a blue laser (488 nm in setup 1; 473 nm in setup 2). Patterned light reflected off the DMD was spatially filtered with a pinhole to select the 0^{th} diffractive order, then the relayed image of the DMD was expanded and projected onto the sample plane of the microscope. We wrote C#, Python, and Arduino software to control the lasers and create spatial patterns for photostimulation (available upon request).

Parameters for optogenetic stimulation: For *Tg(dbh:KalTA4);Tg(UAS:CoChR-eGFP)* fish on setup 1, the excitation intensity was 0.17 mW / mm^2 and the stimulation duration was 3 s of 10 ms pulses at 10 Hz. For *Tg(gfap:opto-α1AR-eYFP)* fish on setup 1, the excitation intensity was 0.42 mW / mm^2; the stimulation duration was 10 s of continuous illumination. For *Tg(gfap:CoChR-eGFP)* fish on setup 2, the stimulation intensity ranged from 0.23 to 0.46 mW / mm^2; the stimulation duration was 3 s of 10 ms pulses at 10 Hz.

Two-photon ablation of cells

For plasma ablation of individual radial astrocytic cells, we used a two-photon laser (Coherent, Chameleon Ultra II). Cells were selected based on their location between rhombomere 2 and rhombomere 6, along the midline of the dorsal hindbrain, and a genetic marker in *Tg(gfap:H2B-GCaMP6f)* fish. Ablation was done with high laser power (930 nm, 500 mW, measured after the objective) directed to a single point on each cell with short exposure time (1 – 4 ms) and 300–400 ms between ablations to prevent thermal damage. After successful ablation, an image stack showed previously bright, round nuclei appeared dim, irregular or fragmented. Cells without this signature were selected again for the next round. Each fish underwent 3–5 rounds of ablation. The experiment started 30-60 min after the last ablation.

Noradrenergic neurons in LC and norepinephrine cluster of the medulla oblongata (NE-MO) were similarly ablated in *Tg(th-P2A-Gal4); Tg(UAS:GCaMP6s)* fish and serotonergic neurons in the dorsal raphe nucleus (DRN) were ablated in *Tg(elavl3:H2B-GCaMP6f)*. In this line, DRN cells were identified by their anatomical location. In control experiments, similar numbers of neurons labeled by *Tg(elavl3:H2B-GCaMP6f)* in nearby brain regions were ablated with the same protocol.

Forebrain lesioning

Fish were embedded in 2% agarose and anesthetized in external solution with tricaine (0.2 mg/mL) at 4 dpf. An incision was made at the top of the forebrain, and a glass pipette (inner diameter ~20 μm) was inserted until it touched the brain. Negative pressure was applied through a tube connected to the glass pipette, and the forebrain was removed by suction. Fish were released from agarose twenty minutes later and returned to the incubator. Behavior experiments were done at 6 dpf, when the forebrain was still largely missing. Siblings were used as controls. Control fish went through the same procedure except that their forebrain was left intact. During testing, two fish of similar body size, forebrain-intact and forebrain-removed, were put in the same rig and recorded simultaneously.

TRPV1-mediated activation of radial astrocytes

For TRPV1-mediated activation (Chen et al., 2016) of radial astrocytes, we injected *gfap:TRPV1-T2A-eGFP* plasmid into embryos from *Tg(gfap:jRGECO1b)* transgenic fish at the 1–2 cell stage. TRPV1 protein expressed sparsely in radial astrocytes. Fish were screened at 3 dpf: larvae with strong, sparse GFP expression in the hindbrain were the 'TRPV1 (+)' group; those without detectable GFP expression were the 'TRPV1(-)' group. Both groups were screened again based on expression of jRGECO1b, and subdivided into four groups: 'TRPV1(+) jRGECO1b(+)'; 'TRPV1(+) jRGECO1b(-)'; 'TRPV1(-) jRGECO1b(+)'; and 'TRPV1(-) jRGECO1b(-)'. All fish were tested behaviorally; jRGECO1b-positive fish were imaged in a light-sheet microscope. For all experiments, fish were recorded for at least 0.5 h, and then capsaicin (Sigma; 5 μM final concentration in system water) or saline was delivered into the recording chamber, and recording continued for 1 to 2 h.

Calcium responses and behavior were quantified in two 10-min windows: from 11 min to 1 min before capsaicin ('before' treatment) and from 10 to 20 min after capsaicin ('after' treatment).

IP_3 receptor blockade

To partially block the calcium concentration increase in radial astrocytes, we inhibited IP_3 receptor-dependent calcium release by loading the inhibitor Xestospongin C (Sigma) (Gafni et al., 1997) near astrocytic cell bodies. Glass pipettes were pulled on a micropipette puller (P-1000, Sutter Instruments), and broken on a microforge (MF900, Narashige), to get a 10 μm-wide tip. This sharp glass pipette was loaded with 5 μL of a mixture of Xestospongin C (100 μM, in external solution) and a fluorescent dye (Dextran, Texas Red, 0.5%, or Dextran, Fluorescein, 0.5%, Thermofisher) to visualize the ejection. The pipette was then inserted through the skin of a paralyzed *Tg(gfap:GCaMP6f)* fish and advanced to the hindbrain ventricle, near astrocytic somata. We first assessed how long the fish spent in a passive state while in open loop for 30 min. Then, pulses (20 psi, 30 ms, inter-pulse-interval 30 s, 10 pulses) were delivered using a pressure ejection system (Picosprizter III, Parker Hannifin). Fish were then switched to the closed-loop condition for ~20 min to allow the drug to take effect and then back to open loop to record the time spent in passivity.

Analysis of fluorescence imaging data

Calcium indicators

Multiple calcium indicators - GCaMP6f, GCaMP6s, H2B-GCaMP6f, jRGECO1b - were used for different purposes: single color imaging, dual-color simultaneous two-population imaging, imaging with optogenetic stimulation. For whole-brain imaging analysis, we tested both the calcium indicators (jRGECO1b and GCaMP6f) in both neurons and radial astrocytes, and found similar relationships between calcium responses and behavior with both indicators.

Summary of Calcium Indicators for Each Experiment

Baseline normalization

For all functional imaging videos, baseline fluorescence was estimated by smoothing each pixel's time series with a sliding-window percentile filter that estimated the 20th percentile of the data in 5-min windows, after subtracting the camera baseline (~100). ΔF/F was then calculated for each pixel's time series (after subtracting camera baseline) by subtracting the baseline from the raw time

series and dividing this difference by the baseline plus an offset of 10, to prevent division by baseline values very close to 0. The addition of an offset to the denominator of the ΔF/F calculation underestimates true ΔF/F but reduces the rate of artifacts.

Extraction of cells from voxel data

We developed a data-processing pipeline to extract populations of cell bodies and neuropil, then cluster these cell segments (called 'cells') into functionally relevant components (cells with similar activity patterns and reproducible anatomical structure), and finally to align and compare cells and components at specific behavioral points and across fish.

For each fish, our analyses began with ANTs 2.1.0 rigid-body registration of all volumes to the average volume (Avants et al., 2010). Then we created an intensity-based brain mask and fully divided the brain into about 1000 spatially contiguous three-dimensional blocks, which overlapped slightly to capture cells on the borders.

We used the Spark cluster computing framework (Zaharia et al., 2010) to parallelize cell-detection across blocks. Our algorithm was based on constrained non-negative matrix factorization. For n voxels, t time points, and c cells, we factorized

$$V_{(n \times t)} \approx W_{(n \times c)} H_{(c \times t)} + X_{(n \times 1)} I_{(1 \times t)} \quad (1)$$

where V is the full spatiotemporal fluorescence matrix for each block, W and H are, respectively, the spatial location and time series of segmented cells, and X and I are a rank-1 spatiotemporal model of the background signal. We set the block size under the assumption that each block would contain 100 tightly packed 6 μm diameter spheres. Thus, we set the number of cells in each block to be 100, and then gradually reduced this number (through iterative multiplication by 0.95) until the system in Equation 1 was not rank-deficient and factorization converged.

We combined local intensity peaks and local correlation coefficients to initialize W (and used a constant value to initialize X); and approximately solved Equation 1 using alternating least-squares (Berry et al., 2007), with at least 10 iterations, and at most 100 iterations or until numerical convergence (defined as a change in the value of the residuals < 0.001).

We imposed spatial and temporal constraints to regularize this factorization, including mean-amplitude normalization of each cell; hard spatial constraints: retaining the largest connected segment within a static 12 μm diameter sphere (centered on a local-intensity peak); and soft sparseness constraints: a sparse projection of the spatial footprint for each cell using the algorithm of Hoyer (Hoyer, 2004), with sparseness,

$$\text{sparseness}(W_i) = \frac{\sqrt{n} - \sum_j |W_{ij}| \Big/ \sqrt{\sum_j |W_i|^2}}{\sqrt{n} - 1} \quad (2)$$

set to be at least equal to the spatial sparseness of a binary 6 μm diameter sphere (these constraints were not applied to the model of the background signal)

The resulting cell representation of whole-brain activity accurately reproduced the raw voxel time series and had increased signal-to-noise ratio due to demixing and denoising. Regions of neuropil and astrocytic processes were factorized similarly to cell bodies, also yielding small patches of voxels with consistent signals.

Clustering cells into components

We clustered segmented cells into functionally relevant components in two steps. First, we used non-negative matrix factorization to reduce the time series for all segmented cells in the brain into low-dimensional components. Specifically, for k cells, t time points, and $m = 60$ components, we factorized

$$H_{(k \times t)} \approx S_{(k \times m)} T_{(m \times t)} \quad (3)$$

where H are time series for all segmented cells in the brain, while S and T are the spatial and temporal low-dimensional components. These components need not be spatially localized, so we substituted local intensity-based initialization for nonnegative double SVD method (Boutsidis and Gallopoulos, 2008) and imposed no spatial constraints on this factorization.

Second, we detected components in this reduced representation. We deemed a component to be functionally relevant when it contained cells with similar activity patterns and showed robust and reproducible anatomical structure across fish (Figures 2D and 2E; Video S2). In contrast, noise components lacked clear spatial structure or were not reproducible across fish.

To evaluate reproducibility, we constructed an average brain template, independently for neurons and radial astrocytes, using the nonlinear registration tool antsMultivariateTemplateConstruction2 (Avants et al., 2010). We registered the spatial component of each fish to this template, and did semi-automated clustering across all components of all fish. We clustered spatial components by binning adjacent voxels of each component, computing the correlation coefficient between all components, thresholding the correlation matrix, and clustering the thresholded correlation matrix using the clique percolation method (Palla et al., 2005), an algorithm that can flexibly assign each component to more than one cluster or to no clusters. We manually fine-tuned this initial clustering by excluding components from clusters if the average spatial correlation of the component with the cluster was too low, and including the component if the average correlation of the component to all components within the cluster was sufficiently high. This step yielded 10-20 neuronal and astrocytic clusters. All components within each cluster were averaged, smoothed, and warped to individual fish space. Figures 2D and 2E shows the 10 group-average components with highest p values (see below), while Video S2 shows all group-average components created in this way for neurons and radial astrocytes.

To avoid misalignment of group-average components in individual fish, we used an additional nonnegative matrix factorization step, which aligned the components more tightly to each fish. Specifically, we refactorized H (Equation 3), with S initialized by and constrained to be within the binary mask of each group-average component. This added step allowed us to combine the consistency of components across multiple fish with the individual spatial variation of components within each fish. Finally, we averaged the activity of cells within the spatial mask of each component in individual fish, and compared this average across active and passive states.

Analysis of component and cell activity around passivity onset

We related neuronal and astrocytic component and cell dynamics to behavior by upsampling all calcium signals to 10 Hz, and registering them to passivity onset, and to the midpoints of bouts preceding this onset. As timings of individual bout sequences varied (relative to passivity onset) across trials, we registered bouts by averaging the relative times of bout sequences across trials and fish and linearly interpolating between individual-trial and average bout-sequence times.

This approach allowed us to study average activity of each component and cell relative to passivity onset (Figures 2F–2M; Video S3). We estimated the increase in calcium during and after passivity onset by comparing a sliding 1 s window of $(\Delta F/F)$ to the baseline, defined as the average over 10 to 5 s before passivity onset. We computed the significance of any increases in calcium by one-tailed Wilcoxon signed-rank test across trials. At this exploratory stage, we sought to identify candidate components and cells associated with passivity onset by computing $-\log_{10}(\text{p value})$, where p values from the Wilcoxon rank-sum were averaged between 1 s to 4 s after passivity onset.

We further analyzed the temporal profile of activity of neurons and radial astrocytes close to passivity onset at the single-cell level, by averaging activity of each segmented cell within a one-second window centered on the peak of each bout, and fitting an exponential function to the activity averaged over the last five bouts before passivity onset (Figure 6A). We interpreted the best-fit exponent of the cell as the rate at which single-cell fluorescence increased before the fish became passive.

Confocal microscopy

Confocal imaging was done using a Zeiss LSM 710, a Zeiss LSM 880 upright confocal, and a Zeiss LSM 800.

Single-cell radial astrocyte tracing

Tg(gfap:jRGECO1b) or *Tg(gad1b:RFP)* fish at 6 dpf were embedded dorsal side up in 2% agarose in a 35 mm Petri dish. The head was exposed by cutting away the agarose above the hindbrain. Fish were then imaged with a two-photon microscope at a wavelength of 1030 nm in the dorsal anterior hindbrain adjacent to the Lateral Medulla Oblongata (L-MO), at the level of rhombomeres 2-3, the approximate location of the rostral cluster of radial astrocytes. Single radial astrocytes were electroporated with 20% Texas Red Dextran or fluorescein Dextran, 3,000 MW, anionic, lysine fixable (Molecular Probes) as described (Koyama et al., 2011). For electroporation, we delivered 150 square pulses of 1 ms duration and 30 V at a frequency of 20 Hz using glass electrodes with an impedance of 240 MΩ. Then fish were released from agarose and transferred to the incubator. After overnight fixation in a 4% solution of paraformaldehyde in phosphate-buffered saline (PBS) pH 7.4 at 4°C, fish were dissected to expose the brain and imaged from the dorsal side on a Zeiss LSM 880 confocal microscope using a 25x objective. Confocal stacks were analyzed with FIJI (ImageJ).

In situ hybridization

Zebrafish larvae at 6 dpf were euthanized with an overdose of MS-222 (tricaine) and fixed overnight in 4% PFA-PBS, pH 7.4 at 4°C. Fish were dissected to expose the brain and processed for whole mount *in situ* hybridization (WISH) using the RNAScope technology by manufacturer protocol (Gross-Thebing et al., 2014). The adra1Bb custom probe was designed by the manufacturer and used on transgenic *Tg(gfap:GCaMP6f)* fish. Fish were then mounted in Vectashield (Vector Laboratories, Burlingame) and imaged on a Zeiss 800 upright confocal microscope with a 25x water immersion objective.

Immunohistochemistry with expansion microscopy

Tissue preparation

Fish brains were dissected out in PBS and fixed in 4% PFA-PBS, pH 7.4 overnight at 4°C, then rinsed well with PBS before antibody labeling.

Antibody staining

Brains were incubated in blocking buffer (10% goat serum, 0.8% Triton X-100 in PBS) overnight at 4°C. Brains were then incubated with primary antibodies chicken anti-GFP (Aves, GFP-1020) and rabbit anti-dsRed (Clontech, 632496) diluted 1:500 in blocking buffer, for 2 days at 4°C, followed by washing in wash buffer (0.3% Tween 20 in PBS) 5x 30 min at room temperature. Brains were incubated in fluorescent secondary antibodies goat anti-chicken Alexa Fluor 488 (Invitrogen, A11039) and goat anti-rabbit Alexa Fluor 594 (Invitrogen, A11037) diluted 1:500 in blocking buffer, for 2 days at 4°C, followed by washing in wash buffer 5x 30mins at room temperature. Brains were then washed and stored in PBS. All antibody staining steps included shaking.

Expansion

Expansion was done as described (Tillberg et al., 2016) (see also Freifeld et al., 2017). AcX was resuspended at 10mg/mL in anhydrous DMSO, aliquoted, and stored desiccated at –20°C for up to several months. AcX aliquots were diluted 1:100 in PBS to produce anchoring solution just before use. Specimens were incubated with at least 100-fold volume excess of anchoring solution, at room temperature overnight, protected from light, without shaking.

Gelation solution (8.6% (w/v) sodium acrylate, 2.5% (w/v) acrylamide, 0.15% (w/v) bisacrylamide, 2M sodium chloride, 1xPBS, 0.01% (w/v) 4HT, 0.2% (w/v) TEMED, and 0.2% (w/v) APS in milliQ water) was prepared as follows: all components except 4HT, TEMED, and APS were mixed to produce StockX, which was aliquoted and stored at −20°C for up to several months. Aliquots were thawed and chilled to 4°C, and then 4HT, TEMED, and APS were added from concentrated stocks (0.5% (w/v) 4HT, 10% (v/v) TEMED, 10% (w/v) APS) just before use. Specimens were incubated with at least 100-fold volume excess gelation solution 2x 10min at 4°C.

During the incubation in gelation solution, chambers were prepared by applying adhesive silicone gaskets (ThermoFisher Scientific, P24743) to plain glass slides and coating the glass bottom of each well with 1 μL poly-lysine coating solution (poly-lysine solution (Ted Pella 18026) with photo-flo (EMS 74257) added up to 0.2% (v/v)), leaving at least 5 min for poly-lysine coating solution to dry onto glass.

Following incubation in gelation solution, specimens were transferred to the middle of chambers, where they adhered to the poly-lysine treated surface, leaving at least 2 mm between each specimen and the chamber wall. Excess gelation solution was removed and replaced with 36 μL gelation solution for each 9 mm diameter chamber. Chambers were sealed with cover glass, which forms a seal with the silicone gasket under gentle pressure. Care was taken to avoid bubbles within 2 mm of specimens. Chambers were then held at 37°C for 2 h to gel and cure specimens. Chambers were moved to 37°C within 30 min of adding APS to the solution to prevent premature gelation.

After gelation, chambers were brought back to room temperature and disassembled. Top cover glass and silicone gaskets were carefully removed, leaving gels adhered to glass slides. Gels were trimmed using a razor blade to a right trapezoidal shape to aid in post-expansion orientation of the specimen. Several microliters of digestion buffer (0.5% (w/v) Triton X-100, 500 mM sodium chloride, 1 mM EDTA, 50 mM Tris pH 8) were applied around the edge of each gel to de-adhere them from the glass surface. Proteinase K (New England Biolabs, P8107S) was added 1:100 to digestion buffer to produce digestion solution. Gels were incubated in at least a 100-fold volume excess of digestion solution overnight, at room temperature, with shaking. Following digestion, gels were washed several times in PBS and kept at 4°C until further use.

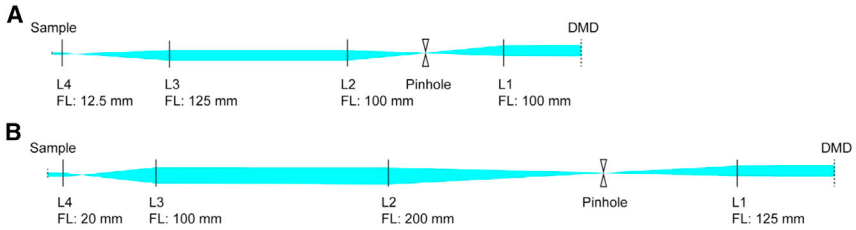
Expansion and imaging

Gels were expanded by washing in water and imaged on a Zeiss Z1 light sheet microscope with standard settings (Figure 3) or a Zeiss LSM 880 confocal microscope (Figure S3). Adjacent volumes were stitched using the Zeiss ZEN software. In Figures 3 and S3, stitching artifacts arising from non-ideal software stitching are indicated with arrowheads and dashed lines.

Materials Used Specifically for Expansion Microscopy

Name	Formal name	Supplier	Cat #
AcX	Acryloyl-X, SE, 6-((acryloyl)amino) hexanoic Acid, Succinimidyl Ester	ThermoFisher Scientific	A20770
Sodium acrylate	Sodium acrylate	Sigma	408220
Acrylamide	Acrylamide	Sigma	A9099
Bisacrylamide	N,N′- Methylenebisacrylamide	Sigma	M7279
4HT	4-Hydroxy-TEMPO	Sigma	176141
TEMED	N,N,N′,N′- Tetramethylethylenediamine	Sigma	T7024
APS	Ammonium persulfate	Sigma	A3678

RNA sequencing



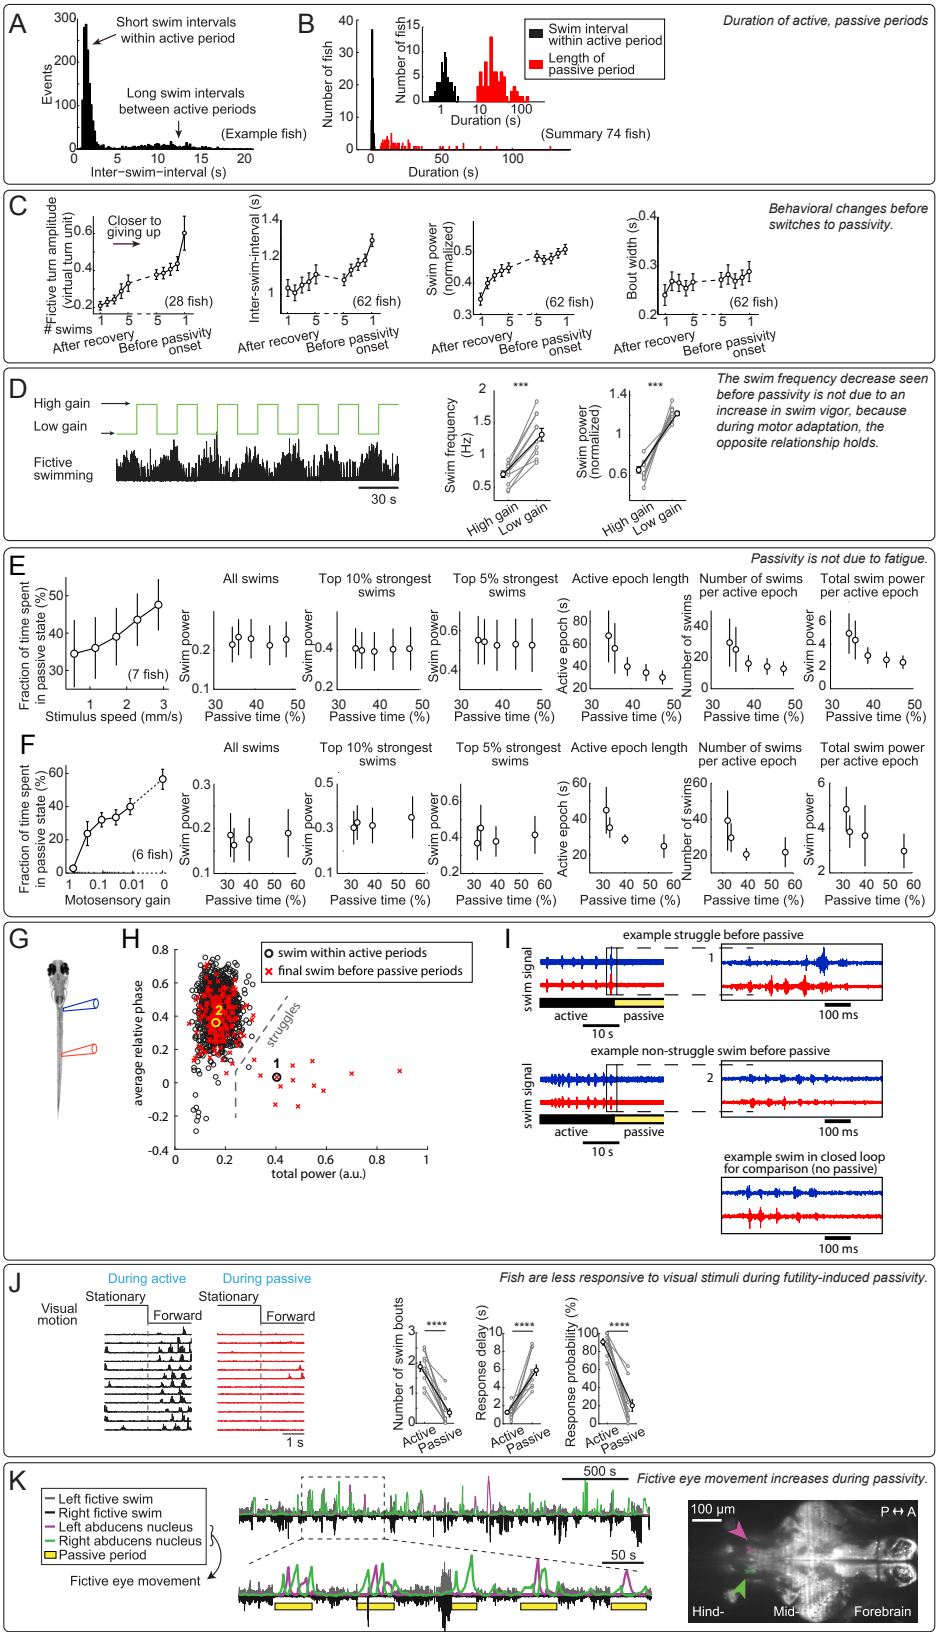
Cell isolation, library preparation, and sequencing

Neurons and radial astrocytes were isolated using methods of Hempel et al. (2007) with minor modifications. Fish were euthanized with 1:30 dilution MS-222/Tricaine in external solution, then placed on ice. Brains were dissected in 1:30 dilution of MS-222/Tricaine in external solution, then digested with Liberase-DH (1 mg/mL; Roche) in external solution for about 1 h. Digested brains were washed three times in external solution with 1:30 dilution of MS-222/Tricaine. Digested brains were triturated as described (Hempel et al., 2007) in external solution containing Tricaine and 2% fetal bovine serum. Cells were isolated by hand. About 300 cells were collected for each sample and lysed in 50 μl PicoPure extraction buffer. RNA was extracted and libraries were prepared as described (Cembrowski et al., 2016). Briefly, cDNA was prepared from DNase-treated RNA using Ovation RNA-seq v2 kit (NuGEN). Barcoded libraries were prepared with Ovation Rapid library kit (NuGEN) and sequenced on a HiSeq 2500 to a depth of about 40 M reads per sample with single-end 100 bp reads.

Gene expression estimation

Sequencing adapters were trimmed from the reads using cutadapt (https://doi.org/10.14806/ej.17.1.200). Trimmed reads were aligned to danRer10 Refgene transcriptome (UCSC). Gene expression estimates were reported as transcripts per million.

Optical Pathway for Optogenetic Stimulation



Optics in the two DMD photostimulation modules. The chief difference between these designs is demagnification of DMD image at focal plane of L4 (objective lens).

(A) Setup 1, photostimulation module in light sheet microscope. This module was used for all experiments that combined optogenetics with calcium imaging. As this module is designed for one photostimulation wavelength, lenses F1-F3 in panel A are singlets (Thorlabs). Final demagnification of DMD chip is 0.1X.

(B) Setup 2, Photostimulation module used in epifluorescence microscope. This module was used for all optogenetic experiments without calcium imaging. As this module is designed for two photostimulation wavelengths, lenses F1 - F3 in Panel B are achromatic doublets (Thorlabs). The final demagnification is 0.32X.

DATA AND CODE AVAILABILITY

The code for cell segmentation and component detection is available at https://github.com/mikarubi/segmentation.

(legend on next page)

Figure S1. Higher-Order Behavioral Effects of Futility-Induced Passivity, Related to Figure 1

(A and B) Distribution of inter-swim intervals in open-loop. Intervals followed a bimodal distribution: short swim intervals occurred within the active period when fish swam once every 1-2 s, and long swim intervals occurred between active periods when the fish stopped swimming (defined as the 'passive period'). (A) Distribution of all inter-swim-intervals from an example fish. (B) Distribution of average inter-swim-intervals during classified active periods (black bars), and average duration of passive periods (red bars) across fish.

(C) Over the course of an active period in open-loop, the animals: 1. made larger turns, and turning amplitude was largest just before passivity onset; 2. swam less frequently, and the longest interval between swims happened just before passivity onset; 3. swam more vigorously, and swimming was on average strongest just before passivity onset; 4. but the duration (width) of swim bouts was not strongly modulated. Error bars, SEM.

(D) Decrease in swim frequency (seen before passivity in C) is not due to an increase in swim power, control for Figure 1I. (*Left*) Motor adaptation assay; low motosensory gain in a closed-loop environment led to more powerful swimming. (*Right*) During low motosensory gain, swim frequency and swim power were both elevated compared to during high motosensory gain. Therefore, the decrease in swim frequency observed as the animal approaches passivity (Figure 1I) was not simply due to a concurrent increase in swim power. (Two-tailed paired t test, ***$p < 0.001$, $p = 8.9 \times 10^{-6}$ for swim frequency, $p = 2.7 \times 10^{-6}$ for normalized swim power. Error bars, SEM)

(E and F) Effects of stimulus velocity and motosensory gain on futility-induced passivity imply that passivity was unlikely to be caused by fatigue. More passivity was caused by (E) faster forward-moving visual stimulus in open loop, or (F) lower motosensory gain in closed loop. Under those conditions, increased occurrence of passivity was not due to more vigorous or more frequent swimming because: similar swim power of individual swims was observed for different velocities or gains, as well as of the top 10% strongest swims and the top 5% strongest swims. On the contrary, more passivity can be associated with smaller amounts of total swim output: shorter active periods, fewer swim attempts, and less total swim power. Together, these results imply that passivity was not caused by fatigue. Error bars, SEM.

(G–I) During transitions from active periods to passive periods, fish occasionally struggle. (G) Experimental setup showing placement of an electrode pair, recording electrical signals from the same side but different segments of the tail (Liao and Fetcho, 2008). (H) Struggles can be identified by the relative phase difference between anterior and posterior electrodes, and power per burst. Final swims before passivity can be non-struggle swims or struggles. On average 13 ± 9% of switches are preceded by a struggle (identified by burst power, n = 5 fish, mean ± SEM). (I) Example of switches preceded by a struggle (top), non-struggle swim (middle), and for comparison, closed-loop swimming (bottom).

(J) Fish were less responsive to visual stimuli during the passive periods. In an assay where, first, passivity was elicited by the usual paradigm, then a static stimulus was presented (2 s), and then pulse of visual motion was presented (2 s), the animals responded far less to the motion pulse if they were in the passive behavioral state. (Two-tailed paired t test, ****$p < 0.0001$, $p = 2.6 \times 10^{-6}$ for swim bout number change, $p = 3.8 \times 10^{-5}$ for response delay, $p = 4.2 \times 10^{-7}$ for response probability. Error bars, SEM) Same data as in Figure 1K.

(K) During the passive periods, calcium activity was seen in neurons in the abducens nucleus (arrows) in animals expressing nuclear-localized GCaMP6f (*Tg(elavl3:H2B-GCaMP6f)*) imaged with a light-sheet microscope. Neurons in the abducens nucleus are known to drive eye movement. Thus, increased activity in this area, alternating between left and right, implies that animals were attempting to move their eyes during the passive periods.

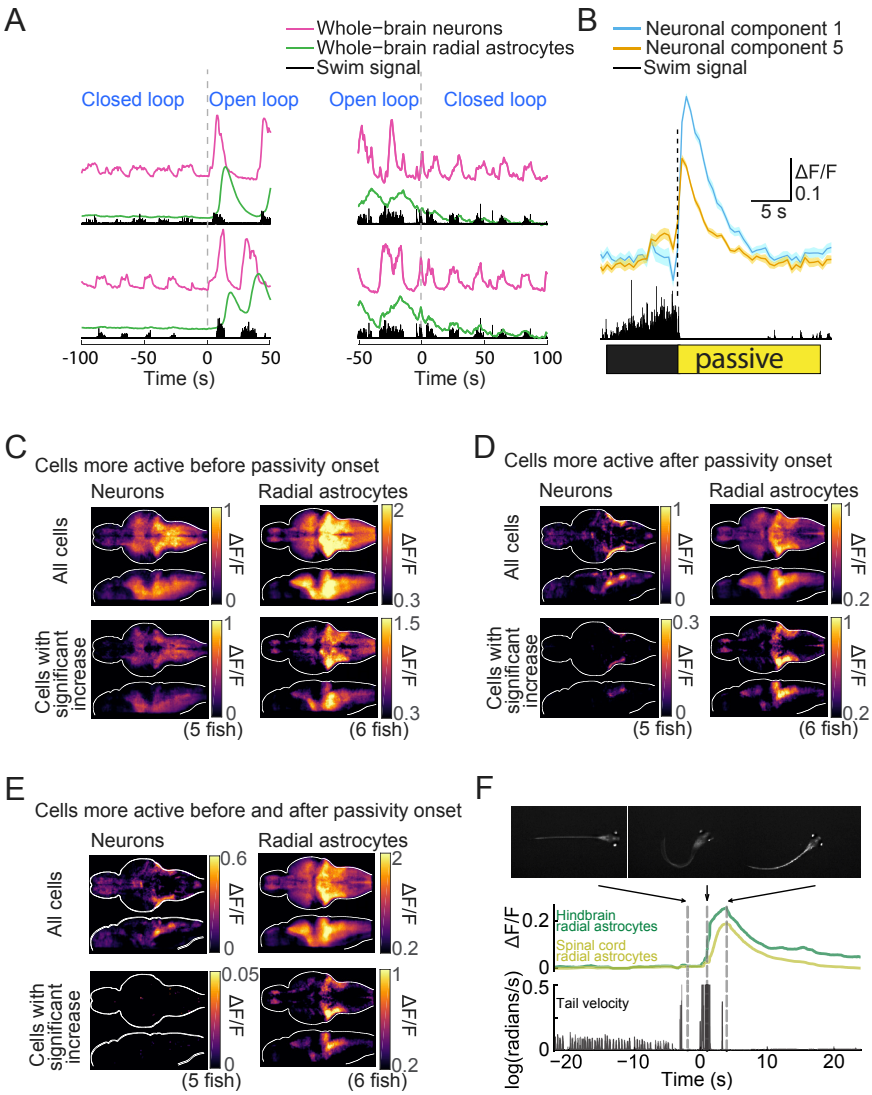


Figure S2. Whole-Brain Activity Elevation before and after Passivity Onset in Both Paralyzed and Non-paralyzed Fish and Passivity in Non-paralyzed Fish, Related to Figure 2

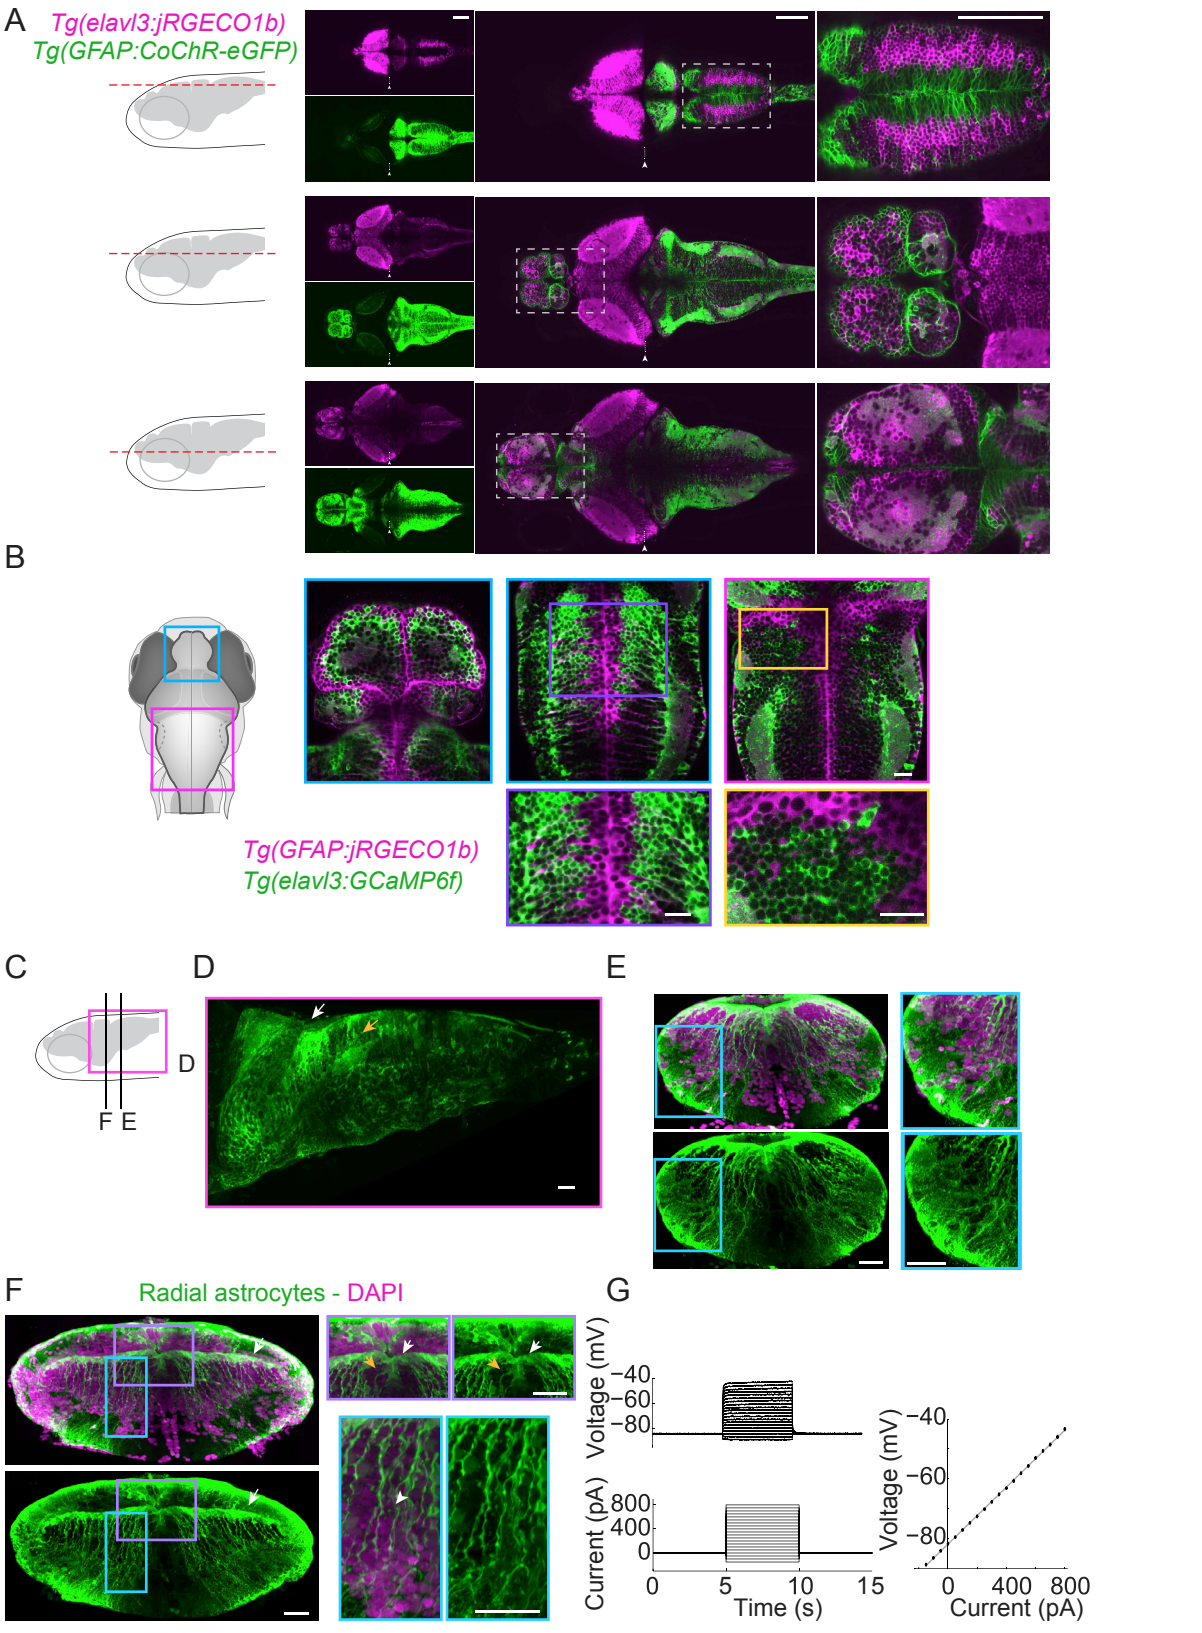
(A) Neuronal and astrocytic activity near the time of open-loop onset (left), and closed-loop onset (right). Signals are averaged across all the neurons or all the radial astrocytes in the brain, and two switches from each type are shown (top and bottom). Neurons showed stronger activity fluctuations during open-loop than during closed-loop, but showed clear activity patterns in both scenarios. In contrast, astrocytic activity fluctuations (calcium) were small before open-loop, but increased before and during passivity. Signals are z-scored.

(B) Average activity of neuronal component 1 and component 5, from the same fish in Figure 2H, triggered by passivity onset. Each trace is the average of 42 switches from active to passive states. Shading represents SEM.

(C–E) Whole-brain neuronal and astrocytic maps for cells showing activity elevation in windows before, after, or both before and after passivity onset (average over 5 fish for neuronal imaging, 6 for astrocytic imaging). Average ΔF/F signals from cells statistically increasing their activity relative to baseline (Methods),



(C) before passivity onset (−1 to 0 s).

(D) after passivity onset (+1 to 4 s).

(E) both before and after passivity onset (−1 to 0 s and +1 to 4 s).

For each panel, top rows show average activity from all cells, and bottom rows show average activity only from cells with significant activity elevation.

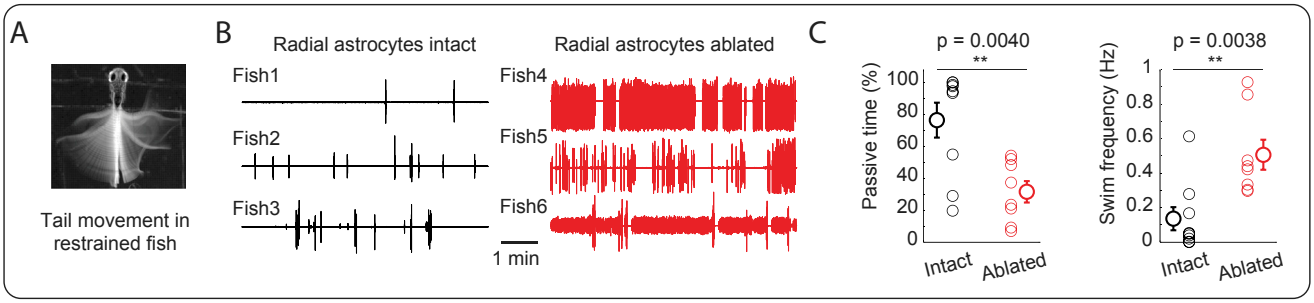
(F) A zebrafish, expressing GCaMP6f in radial astrocytes, was placed in agarose. The agarose was slowly coagulating, but never fully prevented tail motion. The fish attempted to swim and the viscous agarose prevented the movement, qualitatively mimicking a reduction in motosensory gain. The animals displayed similar passivity as in the virtual reality assay. Calcium levels followed a similar pattern as was seen in futility-induced passivity in virtual reality. Calcium activity also increased in the spinal cord, but with a delay.

(legend on next page)

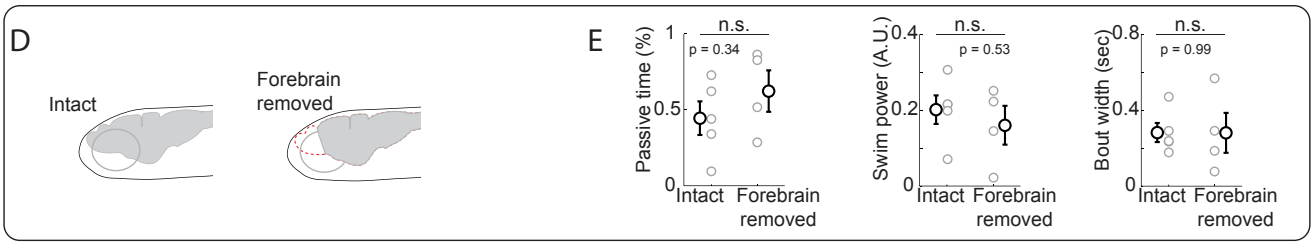
Figure S3. Anatomical and Electrophysiological Properties of Radial Astrocytes Projecting to the L-MO, Related to Figure 3

(A) Distinct expression patterns of CoChR-eGFP driven by the *gfap* promoter and jRGECO1b driven by the *elavl3* promoter suggests that the *gfap*-driven expression was largely restricted to radial astrocytes. Three columns represent three sections arranged from dorsal to ventral across the brain, indicated by the horizontal dashed lines in the schematic at the top of each column. *Row 1*, separated channels for CoChR-eGFP and jRGECO1b (the green channel was overexposed in order to visualize the low-level fluorescence in the tectum); *Row 2*, merged view of those two channels; *Row 3*, zoomed-in view of the region outlined by dashed lines in *Row 2*. Arrowheads indicate microscopy software stitching artifacts. Scale bars, 100 μm.

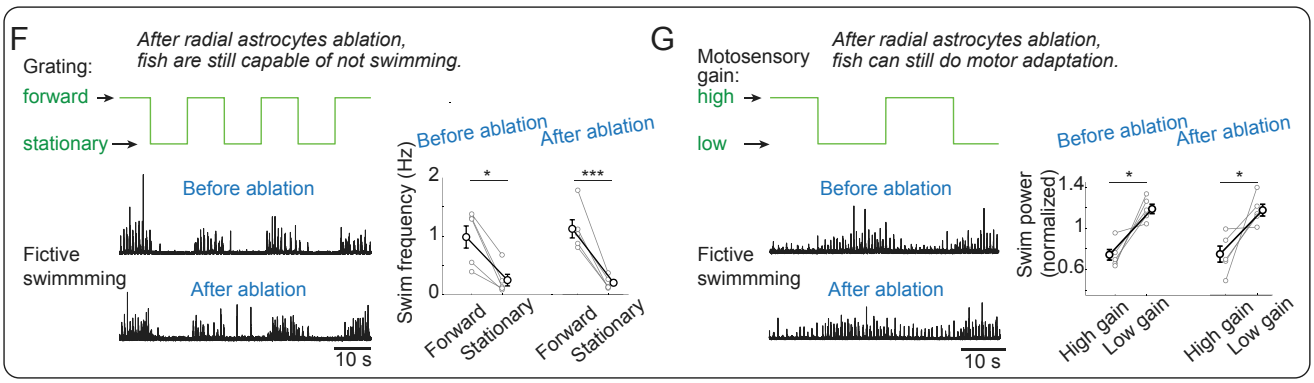
(B) Distinct expression patterns of jRGECO1b driven by the *gfap* promoter and GCaMP6f driven by the *elavl3* promoter, the combination being used for simultaneous imaging of radial astrocytes and neurons. Scale bars, 20 μm.



(C) Schematic side view of the fish brain showing the position of the panel (D) and the cross sections in (E) and (F).



(D) Side view of a section of the hindbrain showing astrocytic cell bodies and processes (white arrow) and the lateral hindbrain neuropil (yellow arrow). Scale bars, 100 μm.



(E) Cross section from a level of the hindbrain that contains the lateral hindbrain (L-MO) (the cyan box inset contains the L-MO). Scale bars, 100 μm.

(F) Cross section at the level of the cerebellum showing the midbrain-hindbrain border (MHB) (arrow). *Top-Left,* Astrocytic cells are shown in green; DAPI staining labels nuclei of all cells (neurons and radial astrocytes). *Bottom-Left,* astrocytic cells only. *Purple box inset*, astrocytic cell bodies (white arrow) can be seen along the dorsal midline and the MHB. Neurons are dark without the GFAP label (yellow arrow). *Cyan box inset,* long astrocytic processes extend dorso-ventrally and terminate in the lateral and ventral gliopil. Scale bars, 100 μm.

(G) Patch-clamp recording of a GCaMP6f-positive cell from a *Tg(gfap:GCaMP6f)* fish shows electrophysiological properties of radial astrocytes: (1) a linear voltage change in response to injected current, (2) more negative resting membrane potential than typical neuronal membrane (−84 mV), consistent with known recordings of radial astrocytes in zebrafish (Li et al., 2015). Error bars, SEM.

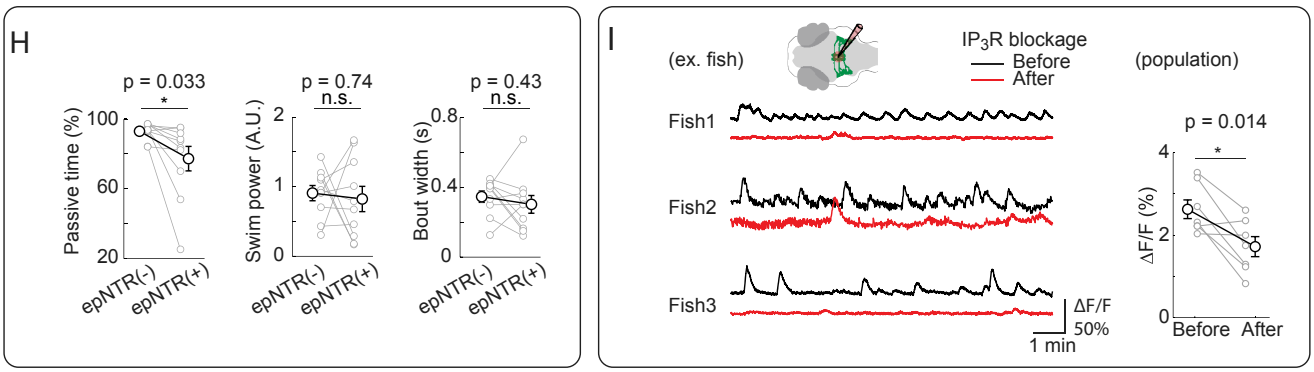


Figure S4. Details of Radial Astrocytes Inactivation, Related to Figure 4

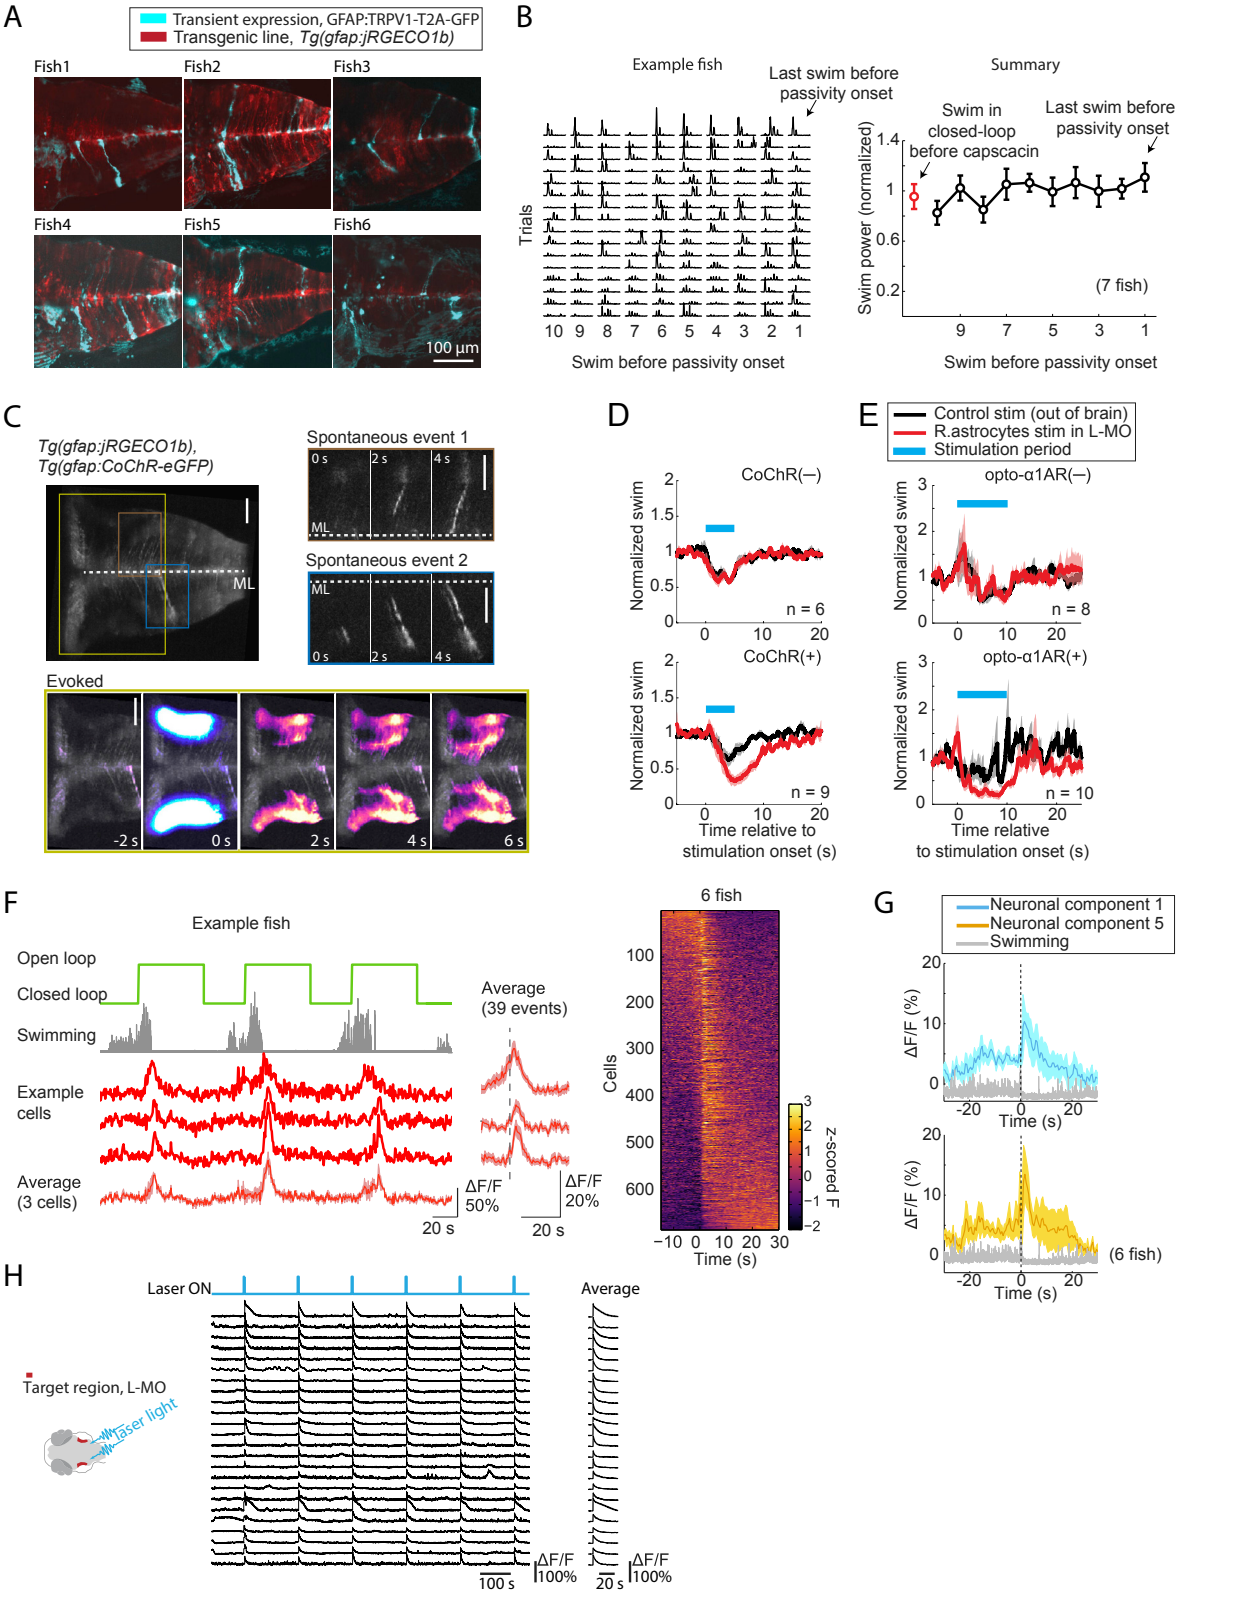
(A–C) Astrocytic ablation in non-paralyzed zebrafish also reduces futility-induced passivity. (A) Fish were embedded in agarose, which was cut away around the tail, eyes and mouth. A time lapse image is shown during vigorous tail movement. (B) Non-paralyzed fish performed futility-induced passivity when head-embedded in agarose. With radial astrocytes intact, swimming occurred rarely. This may be due to the lack of visual feedback during tail movement, as well as the perception of pressure on the upper section of the trunk and head during tail movement. After laser ablation of radial astrocytes, the animals swam much more often. (C) Population data, showing a decrease in time spent passive and an increase in average swim frequency after astrocytic ablation (two-tailed non-paired t test, $^{**}p < 0.01$, $p = 0.0040$ for passive time, $p = 0.0038$ for swim frequency). Error bars, SEM.

(D and E) Removing the forebrain doesn't decrease passivity during open-loop. Removing the forebrain (D, Methods) did not reduce passivity during open-loop (E), showing that non-specific brain damage, of neurons or radial astrocytes, was not the reason for the reduction in passivity. Fictive swimming behavior was similar between the forebrain intact and forebrain-removed siblings (two-tailed non-paired t test). Error bars, SEM.



(F and G) Animals with radial astrocytes ablated can still perform motor adaptation and are still capable of not swimming. (F) When presented with forward visual motion alternating with a stationary stimulus, animals swam little during the stationary periods, both before and after astrocytic ablation, showing that ablation of radial astrocytes does not affect the ability of the animals to stop swimming. (G) Animals performed motor adaptation in a closed-loop environment, before and

(legend continued on next page)

after astrocytic ablation, showing that ablation of radial astrocytes does not affect the ability of the animals to modulate swim vigor. (Two-tailed paired t test, *$p < 0.05$, ***$p < 0.001$, $p = 0.014$ for before ablation, $p = 9.8 \times 10^{-4}$ for after ablation in (F); $p = 0.013$ for before ablation, $p = 0.042$ for after ablation in (G)). Error bars, SEM.

(H) Chemogenetic injury to radial astrocytes leads to a decrease in passive periods but leaves other swim behavior unchanged. The addition of a low concentration of the prodrug metronidazole (10 mM, incubation 8 h) (Tabor et al., 2014) caused intracellular damage to radial astrocytes in *Tg(gfap:epNTR)* fish that expressed nitroreductase in astrocytic cells. (Two-tailed paired t test, *$p < 0.05$, $p = 0.033$ for passive time, $p = 0.74$ for swim power, $p = 0.43$ for bout width). Error bars, SEM.

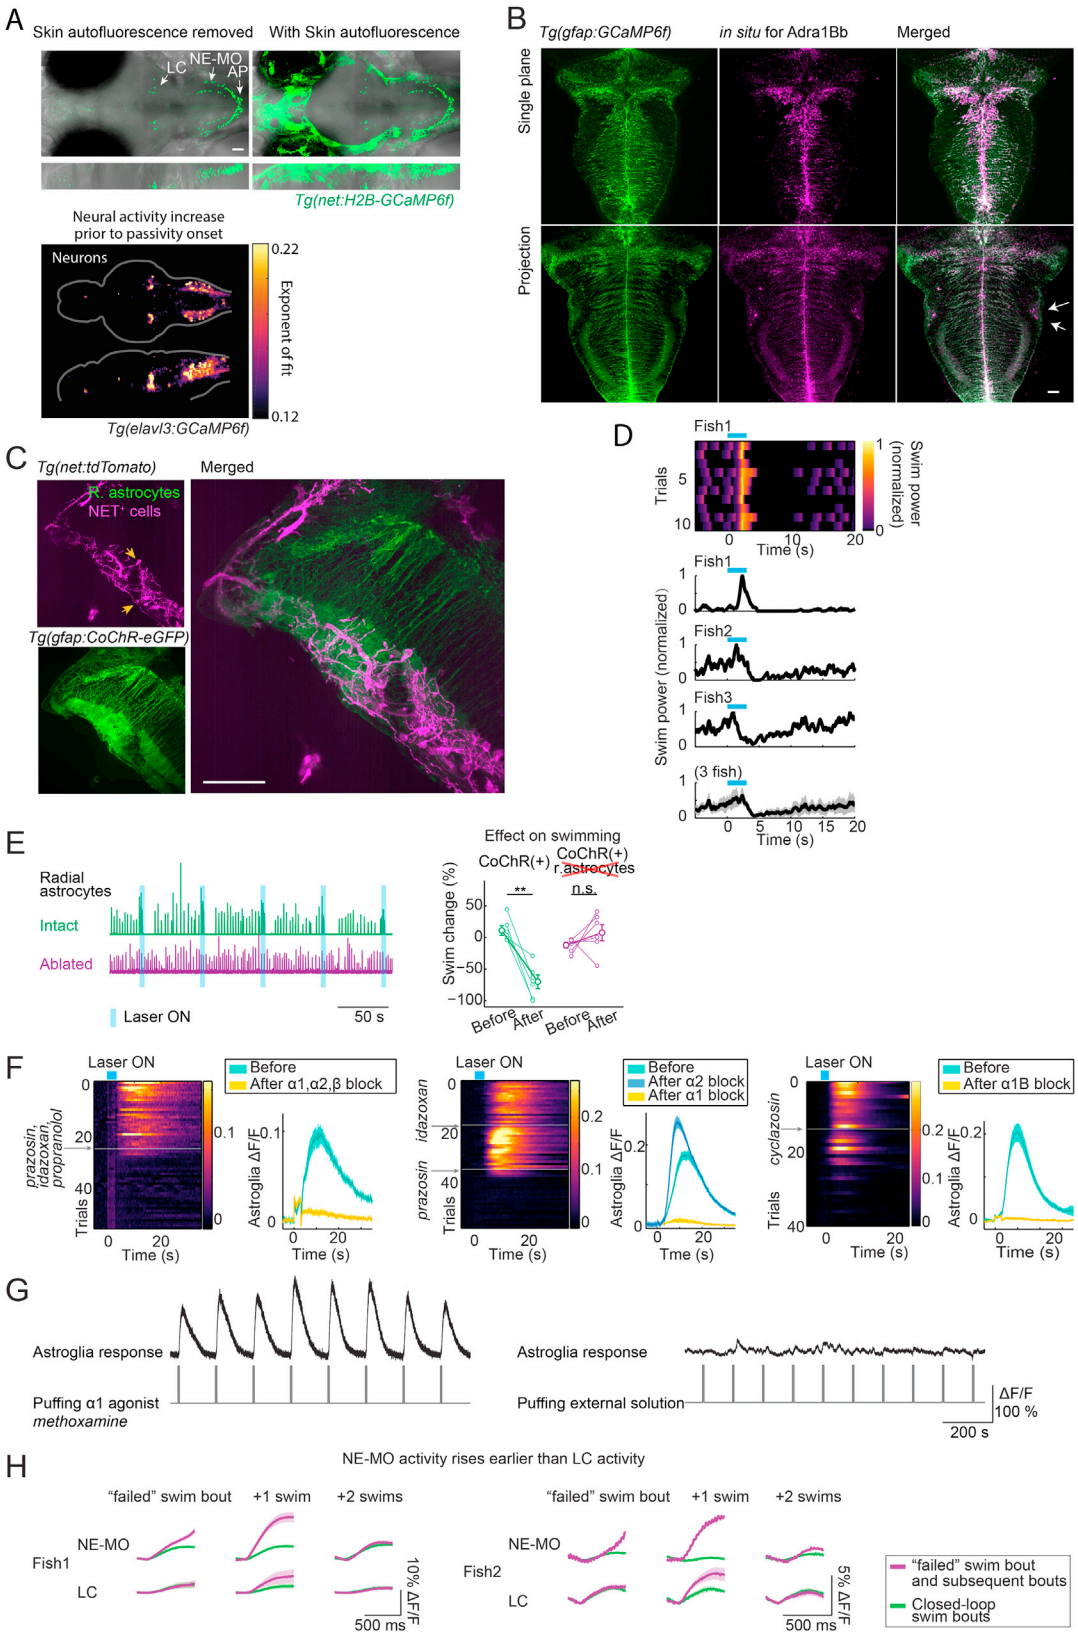
(I) Blocking inositol 1,4,5-trisphosphate receptor (IP_3R) reduces calcium activity in L-MO astrocytic cells during open loop. *Left,* calcium signals in astrocytic processes in the L-MO before (black) and after (red) injection of the IP_3R inhibitor, showing that calcium signals were reduced by the blockade of IP_3R. *Right,* population data showing that the reduction in calcium signal was consistent across animals. (Two-tailed paired t test, *$p < 0.05$, $p = 0.014$). Error bars, SEM.

(legend on next page)

Figure S5. Details of Chemogenetic and Optogenetic Activation of Radial Astrocytes, Related to Figure 5

(A) Sparseness of expression of TRPV1. Maximum intensity projections along the dorsal-ventral axis of hindbrain volumes acquired with a light sheet microscope show that TRPV1 (Chen et al., 2016) channels (introduced into the fish by injection of a *gfap:TRPV1-T2A-GFP*, plasmid into *Tg(gfap:jRGECO1b)* transgenic embryos) were sparsely expressed in radial astrocytes. Expression was seen in about 10-50 astrocytic cells per animal, but opening of the TRPV1 channel with capsaicin activated a much wider population of glial cells (at least hundreds, likely through communication between radial astrocytes). Expressing cells showed the morphology of hindbrain radial astrocytes, with somata along the midline and processes extending laterally and then ramifying. (Note, the images show some contamination from skin autofluorescence. Also note, the jRGECO1b expression was more patchy than usual, likely because the co-injected *Tol2* transposase removed the *jRGECO1b* transgene from the genome of some cells.)

(B) Artificially activating radial astrocytes induces passivity without increasing swim vigor, consistent with a role for radial astrocytes in specifically suppressing swimming. Passivity was caused in closed-loop by applying capsaicin to fish that expressed TRPV1 (Chen et al., 2016) in radial astrocytes. In the swim bouts just prior to TRPV1-mediated passivity, swim vigor did not increase as it did during futility-induced passivity (Figure S1C) – rather, swim vigor stayed at a similar level as swims in closed-loop without capsaicin, showing that radial astrocytes caused passivity independently of increases in swim vigor. In example fish (left panel), each row represents the final 10 swims of an active period before the fish switched to a passive state. Error bars, SEM.



(C) Optogenetic stimulation during functional imaging of radial astrocytes shows that exciting these cells can cause spatially propagating calcium activity. Top row: after optogenetic excitation of astrocytic processes in the L-MO, a wave of calcium can be seen propagating from the site of excitation to the astrocytic cell bodies located along the midline. The time course of evoked activity resembles spontaneous activity of single astrocytic cells (top right), which suggests that optogenetic stimulation is sufficient to drive an endogenous calcium-dependent excitatory pathway in radial astrocytes. Scale bars, 20 μm.

(D and E) Optogenetic stimulation of L-MO astrocytic processes suppresses swimming. (D) *Top:* CoChR-negative controls showed no difference in behavior when the L-MO was stimulated or light was targeted outside of the brain (targeted to the ear, chosen because it is very close to the L-MO but outside the brain). A small response to the blue light was present if either the L-MO or the ear was targeted. *Bottom:* The same experiment in animals expressing CoChR in radial astrocytes showed a difference in behavior, with L-MO stimulation leading to a prolonged suppression of swimming. In total 30 pulses with a width of 10 ms and inter-pulse-interval of 90 ms were delivered for each stimulation (Methods). Shading represents SEM (E) Stimulation in Opto-α1-AR expressing animals similarly showed a suppression of swimming. A continuous 10 s of light stimulation was delivered for each stimulation (Methods). Shading represents SEM.

(F) GABAergic neurons in L-MO activated during switches to passivity. Left, fish switching to the passive state after entering open-loop, with activity increases in GABAergic neurons in L-MO at the time of switches. Right, summary of all GABAergic neurons in L-MO from 6 fish. Cells are ordered by the center of mass along the time axis. Shading represents SEM.

(G) Capsaicin activation of astrocytic calcium causes an increase in neuronal activity in L-MO neurons, consistent with the activation of GABAergic neurons in L-MO after astrocytic stimulation (Figure 5R). Shading represent SEM.

(H) Optogenetically stimulating radial astrocytes causes increases in neuronal activity in L-MO neurons. Shading represents SEM.

(legend on next page)

Figure S6. Calcium Signals in Noradrenergic Neurons Increase before Switches to Passivity, Noradrenergic Receptors Are Highly Expressed and Co-localized with Radial Astrocytes in the Lateral Hindbrain, Activation of Noradrenergic Neurons Can Elicit a Transient Increase in Motor Vigor, and Coding for Swim Failures in Different NE Nuclei, Related to Figures 6 and 7

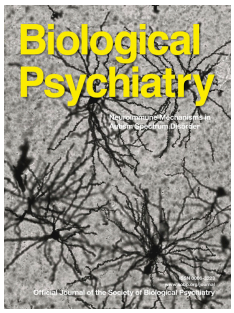
(A) *Top:* The nuclei of noradrenergic (NE) neurons (Farrar et al., 2018) are labeled in *Tg(net:H2B-GCaMP6f)* fish. *Bottom:* The neurons which increase their activity fastest prior to passivity onset overlap with the regions where the somata of noradrenergic cells, including the locus coeruleus (LC) and the NE cluster of the medulla oblongata (NE-MO), are located. Imaged line in the bottom panel is *Tg(elavl3:GCaMP6f)*. For easier visualization of noradrenergic cells, skin auto-fluorescence was removed manually in the top-left panel.

(B) Adrenergic receptor 1Bb expression visualized through *in situ* hybridization. The lateral hindbrain (L-MO) showed high levels of adra1Bb receptor expression (arrows). The receptors can also be seen to line the astrocytic processes that run medial-lateral, consistent with RNA-seq results (see Table S2). The projection is over a 40 μm thick section.

(C) Maximum intensity projection over 50 μm at the level of the L-MO of a *Tg(gfap:CoChR-eGFP); Tg(net:tdTomato)* fish that was expanded 4× through expansion microscopy to show a dense network of noradrenergic fibers expressing the norepinephrine transporter (NET) intertwined with glial processes in the L-MO. The section also shows the cell bodies of noradrenergic neurons (yellow arrows) located at the along the length of the medulla showing that indeed, noradrenergic neurons of the medulla oblongata (NE-MO) project to the L-MO.

(D) Photostimulating NE-MO can briefly potentiate swimming. In closed-loop, optogenetically stimulating NE-MO first increased swim vigor before it suppressed swimming. *Top*, single trials from an example fish. *Bottom,* mean swim power change from 3 example fish and the average from these 3 fish. Shaded region represents SEM.

(E) Photostimulating NE-MO no longer suppresses swimming after ablation of radial astrocytes in L-MO.



(F) Blocking α1 adrenergic receptors, but not α2 adrenergic receptors, abolishes the activation of radial astrocytes in L-MO by NE-MO stimulation. Optogenetic stimulation of NE-MO activates radial astrocytes in L-MO, and this activation was abolished by either adding a mixture of antagonists targeting multiple subtypes of adrenergic receptors (*left*, prazosin for α1, idazoxan for α2, propranolol for β), by an antagonist of α1 adrenergic receptors alone (*middle*), or by an antagonist of α1B adrenergic receptors alone (*right*), but not by an antagonist of α2 adrenergic receptors (*middle*). Shading represents SEM.

(G) Puffing methoxamine, an agonist of the α1 adrenergic receptor, triggered calcium responses in radial astrocytes in L-MO (*left*). Puffing external solution didn't trigger a response (*right*).

(H) Calcium activity in the NE-MO represents swim failures (Figure 7A). Calcium activity in the LC also represents swim failures, but only on the subsequent swim bout; this response may be downstream of the response in the NE-MO. The signals were aligned by subtracting the fluorescence right before the swim onset. Shading represents SEM.

Scale bar in (A-C): 50 μm.

Journal Pre-proof

Abstract

Background: Traumatic experiences, such as conditioned threat, are coded as enduring memories that are frequently subject to generalization, which is characterized by (re-) expression of fear in safe environments. However, the neurobiological mechanisms underlying threat generalization following a traumatic experience and the role of stress hormones in this process remain poorly understood.

Methods: We examined the influence of glucocorticoid hormones on the strength and specificity of conditioned fear memory at the level of sparsely distributed dentate gyrus (DG) engram cells in male mice.

Results: We report that elevating glucocorticoid hormones after fear conditioning induces a generalized contextual fear response. This was accompanied by a selective and persistent increase in the excitability and number of activated DG granule cells. Selective chemogenetic suppression of these sparse cells in the DG prevented glucocorticoid-induced fear generalization and restored contextual memory specificity, while leaving expression of auditory fear memory unaffected.

Conclusions: These results implicate the sparse ensemble of DG engram cells as a critical cellular substrate underlying fear generalization induced by glucocorticoid stress hormones.

Journal Pre-proof

Introduction

Stressful and emotionally arousing events are generally remembered well (*1*). Robust memory retention is highly adaptive but comes at increasing cost when memories lose their specificity. Memory encoding and/or processing under stressful circumstances can result in generalization of fear expression in which memories are expressed promiscuously, even in safe situations and/or in the absence of predictive cues, as exemplified by posttraumatic stress disorder (PTSD) or generalized anxiety disorders (*1*–*3*).

Stressful experiences activate the Hypothalamus-Pituitary-Adrenal (HPA)-axis and the release of glucocorticoid hormones (cortisol in humans, corticosterone in rodents) from the adrenal cortex (*4*). Glucocorticoid hormones alter neuronal function by activating high affinity brain mineralocorticoid receptors (MRs) and lower affinity glucocorticoid receptors (GRs) (*5*, *6*). Via these receptors, glucocorticoid hormones rapidly and persistently increase glutamatergic synaptic transmission, which is critical for synaptic plasticity and learning and memory (*6*–*9*). Behaviorally, glucocorticoid hormones facilitate memory consolidation, extinction and habitual learning (*1*, *10*, *11*). In addition, glucocorticoid hormones have also been reported to modify memory contextualization which may confer memory generalization (*12*, *13*).

Specific memories are encoded by small populations of cells, also known as ‘engram cells’, that are activated during specific learning epochs (*14*–*16*). The hippocampal dentate gyrus (DG) is strongly involved in spatial aspects of memory processing and learning-activated engram populations in this region support the consolidation and expression of contextual fear memories (*17*–*19*). Here, we examined whether glucocorticoid levels affect the specificity of contextual fear memory through changes in the size and physiological properties of the hippocampal DG engram cell population (*20*).

Materials and Methods

Study design

Wildtype (C57BL/6J; WT) mice (Harlan, The Netherlands) and Arc::dVenus mice that were backcrossed for more than 10 generations into C57BL/6J mice (*21*) were used. Experiments were performed during the light phase, using male adult mice (8–12 weeks). Mice were individually housed for 14 days prior to the experiments. All experiments were conducted under EU directive 2010/63/EU for animal experiments and were approved by the animal welfare committee of the University of Amsterdam. Mice were maintained under standard housing conditions (temperature 20-22 °C, 40-60% humidity) on a 12 h light/dark cycle with standard chow and water available *ad libitum*. Assignment to treatment condition, data collection and data processing was conducted at random, by an experimenter blind to the experimental condition. Sample size was determined *a priori* by conducting a power analysis. All experimental procedures were performed using independent cohorts of mice.

Fear conditioning

Fear training involved placing mice into a conditioning chamber, and, 3 min later, presenting three co-terminating presentations of a tone conditioned stimulus (CS) (30s, 20.8 kHz, 82 dB) and a foot shock unconditioned stimulus (US) (2s, 0.2 mA). This mild conditioning paradigm was selected to avoid potential ceiling effects on behavior after corticosterone injections (*22*, *23*). During testing mice were place in the same (context A) and/or a novel context (context B) and freezing was assessed. See Supplementary Materials and Methods for details.

Drug treatment

Corticosterone (Sigma) (dissolved in 5% EtOH, final dose: 2 mg/kg, injection volume: 5 µl/g body weight) was injected intraperitoneally (i.p.) immediately following fear conditioning. RU486 (Sigma) (dissolved in 10% EtOH in peanut oil, final dose: 10 mg/kg, injection volume:

5µl/g body weight) was injected i.p. immediately following conditioning. The corresponding vehicle solution was administered to control group accordingly (*22*).

Immunohistochemistry

Sections were stained for Arc and c-fos as described in the Supplementary Materials and Methods.

Recording Action Potential (AP) Frequency

Mice were left undisturbed for 1h after fear conditioning and injections. Mice were sacrificed by acute decapitation and brains were quickly removed and prepared for whole cell recordings in the DG in current clamp mode as described in the Suppl. M&M.

Recording miniature excitatory postsynaptic currents (mEPSCs)

Mice were left undisturbed for 5h after fear conditioning and injections. Subsequently, mice were sacrificed by acute decapitation and brains were quickly removed and prepared for mEPSC recordings in the DG as described in the Suppl. M&M.

Stereotactic microinjections for viral-TRAP

AAV-Fos::CreER^{T2} (titer: 1.2 x 10^{12}) and Cre-dependent AAV-hSyn:DIO-hM4Di-mCherry and AAV-hSyn::DIO-mCherry (titer: 5-6 x 10^{12}) were packaged as serotype 5 virus. A virus mixture of AAV5-Fos::CreER^{T2} and Cre-dependent AAV (ratio 1:500, AAV-Fos-CreER^{T2} was injected at a final titer of 2.4 x 10^{9}) (*24*, *25*) was infused bilaterally in the DG using microinjection glass needles (0.5 µl; flow rate: 0.1 µl/min; AP = -2.2; ML= ±1.2; DV= -2.2, relative to Bregma).

4-Hydroxytamoxifen (4OHT) treatment

4OHT (H6278, Sigma-Aldrich Chemie N.V., The Netherlands) (50 mg/ml 4OHT dissolved in DMSO (D8148, Sigma-Aldrich Chemie N.V., The Netherlands) and diluted 10x in saline containing 2% Tween80 (P1754, Sigma-Aldrich Chemie N.V., The Netherlands) and 10x in

saline; final concentration: 2.5 mg/ml 4OHT, 5% DMSO and 1% Tween80 in saline) was injected 2h after training in hM4Di-mCherry and control mice. The final dose was 25 mg/kg.

Chemogenetic intervention

Clozapine N-oxide (CNO, BML-NS105, Enzo LifeSciences, Brussels) (dissolved in saline; final dose: 5 mg/kg, injection volume 10 µl/g body weight) was injected i.p. 30 min before a retrieval session in both mCherry and hM4Di-mCherry mice.

Statistical analysis

Data were analyzed using SPSS 22.0 (IBM software). All data are expressed as mean + SEM. Data were considered statistically significant when $p<0.05$ and were tested two-sided. Outliers were determined using a Grubb's test, removing a maximum of 1 data point. Independent-samples t-tests were performed to assess differences between saline and corticosterone-treated mice. When assumption of normality was not met (based on Shapiro-Wilk test), Mann-Whitney test was conducted. A 2x2 ANOVA was performed to assess the interaction between two factors (treatment x context or treatment x cell type), with post-hoc Tukey testing.

Journal Pre-proof

Results

Corticosterone induced fear memory generalization

Mice underwent fear conditioning by 3 mild footshocks (0.2 mA) paired with a discrete tone, immediately followed by systemic administration of corticosterone (2 mg/kg) or saline (**Fig. 1A**). As expected, we observed a conditioning-induced increase of plasma corticosterone levels, which was even further elevated and prolonged in mice receiving post-training corticosterone administration (**Suppl. Fig. 1**).

Freezing was comparable between saline and corticosterone-injected mice during re-exposure to the training context 24 hours after conditioning (**Fig. 1B**) ($t(14)=0.24$, $p=0.82$). In contrast, mice receiving corticosterone immediately following conditioning exhibited

significantly higher freezing to a distinct context (neutral context B), in both the presence and absence of the conditioned tone (**Fig. 1C**) ($F(1,28)=77.13$, $p<0.0001$; post hoc: saline-baseline vs. CORT-baseline: $p=0.02$; saline-tone vs. CORT-tone: $p=0.002$). Moreover, corticosterone injection significantly increased contextual fear generalization, which was quantified as the ratio of context-evoked freezing in context B (novel context) relative to context A (training context) (**Fig. 1D**) ($t(14)=2.84$, $p=0.013$). Although absolute freezing to the tone was higher in corticosterone-treated mice, the relative increase in freezing during the tone compared to baseline freezing in context B was similar between saline and corticosterone-treated mice (**Fig. 1E**) ($t(14)=1.61$, $p=0.13$), indicating that the increase during the tone was caused by a generalized fear response in the novel context.

We next examined whether the effect of corticosterone on generalization of conditioned fear was mediated by activation of glucocorticoid receptors (GRs). Co-administration of the GR antagonist RU486 prevented the effect of corticosterone on freezing in a neutral context (**Fig. 1F**) ($F(1,28)=17.46$, $p=0.0003$, post hoc: Veh-Saline vs. veh-CORT: $p<0.0001$; Veh-CORT vs. RU486-CORT: $p<0.0001$) as well as to the tone (**Fig. 1G**) ($F(1,28)=5.89$, $p=0.02$, post hoc: Veh-Saline vs. veh-CORT: $p=0.004$; Veh-CORT vs. RU486-CORT: $p<0.0001$). Furthermore, freezing in context A and the enhanced freezing in neutral context B following corticosterone treatment was absent in mice that underwent the same paradigm, but without receiving foot shocks during exposure to context A (**Fig. 1H-K**). Together, these results show that increased corticosterone levels immediately after fear conditioning subsequently results in a generalized fear response in a neutral context. Moreover, we show that the effect of corticosterone is mediated through activation of GRs.

Corticosterone enhanced the size of a fear engram cell population

In order to identify how corticosterone triggered memory generalization, we examined neuronal activation in the DG, a brain region that is strongly involved in contextual fear memory (17–19). For this, mice underwent fear conditioning followed by corticosterone or

saline injection. Ninety minutes after conditioning, brains were isolated and immunostained for c-fos, an immediate early gene and molecular marker of recent neuronal activation (*26*) (**Fig. 2A**). The number of neurons expressing endogenous c-fos was increased in the DG of corticosterone-treated mice at 90 minutes after training compared to saline-treated animals (**Fig. 2B,C**) ($t(10)=7.8$, $p<0.0001$). To further characterize the neuronal population that was activated by fear conditioning, we used a transgenic mouse with destabilized Venus fluorescent protein (dVenus) expression under control of the Activity Regulated Cytoskeleton Associated Protein (Arc) promotor (Arc::dVenus mice) (21), which allows for visualization and characterization of activated neurons in the DG for at least 24 hours after conditioning (17). At 90 minutes after fear conditioning, we observed an increase in the number of dVenus labeled cells in corticosterone-treated animals (**Fig. 2D,E**) ($t(14)=3.0$, $p=0.009$). After context exposure alone (without the delivery of a foot shock), corticosterone did not increase the number of c-fos or dVenus labeled cells in the DG compared to control mice (c-fos: $t(14)=1.8$, $p=0.10$; dVenus: $t(14)=0.06$, $p=0.95$) (**Fig. 2F-J**). Ninety minutes after fear conditioning, we observed significant colocalization of cells expressing c-fos and endogenous Arc ($t(15)=22.55$, $p<0.0001$), as well as of the cells co-expressing c-fos and dVenus ($t(14)=18.6$, $p<0.0001$) (**Fig. 2K-M**), indicating that these molecular markers represent, to a large extent, the same cellular population, consistent with what has been reported previously (17). Interestingly, we found that the number of Arc::dVenus positive cells was still increased in corticosterone-treated mice at 24 hours after training compared to control animals (**Fig. 2N-P**) ($t(30)=4.92$, $p<0.001$), suggesting that elevated corticosterone levels during the first hours after conditioning persistently increased the size of the DG engram population.

Upon retrieval (**Fig. 2Q**), corticosterone-injected and saline-injected mice showed comparable numbers of c-fos$^+$ cells in context A (**Fig. 2R**) ($F(1,25)=10.58$, $p=0.003$; post hoc: saline-Context A vs. CORT-Context A: $p=0.99$). In contrast, corticosterone-injected mice exhibited a larger number of c-fos$^+$ cells than saline-injected mice in context B (**Fig. 2R**)

(saline-Context B vs. CORT-Context B: p<0.001). To assess whether training-activated neurons were re-activated upon exposure to context A or B, we used the long-lasting detectability of dVenus in the DG to examine re-activation during memory retrieval. Importantly, at 90 mins after memory retrieval in either context A or context B (**Fig. 2Q**), the density of dVenus$^+$ neurons was equivalent to the density in the absence of a retrieval session (see **Fig. 2P**; main treatment effect: F(1,40)=26.73, p=<0.0001; treatment x test interaction effect: F(2,40)=0.17, p=0.84) (**Fig. 2S**), indicating that retrieval did not alter the size of the training-induced dVenus$^+$ population. In context A and B, we observed preferential expression of c-fos within the dVenus$^+$ populations compared with the dVenus$^-$ populations after saline and corticosterone treatment (main effect cell type: context A: F(1,24)=578.8, p<0.0001; context B: F(1,24)=320.5, p<0.0001). However, corticosterone-injected mice exhibited increased colocalization of c-fos$^+$ and dVenus$^+$ neurons in the DG after exposure to context B compared with saline-treated mice (treatment x cell type interaction effect: F(1,24)=14.22, p<0.001, post hoc: saline-dVenus$^+$ vs. CORT-dVenus$^+$: p<0.0001) (**Fig. 2T,V**), whereas this did not differ between groups after exposure to context A (treatment x cell type interaction effect: F(1,24)=1.03, p=0.32) (**Fig. 2T-U**). Importantly, colocalization between c-fos$^+$ and dVenus$^+$ cells was significantly higher than chance level in Context A for both groups, and higher than chance level in Context B for the CORT-treated animals (**Suppl. Fig. 2**). These findings are consistent with a less precise contextual representation of the memory engram and fear generalization resulting from post-training corticosterone.

Corticosterone selectively enhanced the excitability of dVenus$^+$ neurons after fear conditioning

Since neural activation and excitability determine neuronal selection into a memory engram (*17*, *27–29*), we used whole-cell patch clamp recordings to further investigate the effects of corticosterone on the physiological properties of activated dVenus$^+$ neurons and non-activated (dVenus$^-$) neighboring neurons at 1 h after conditioning. Corticosterone injection

after training did not affect membrane resistance, input resistance, minimum current intensity, membrane capacitance or access resistance differently in dVenus$^-$ and dVenus$^+$ neurons (**Suppl. Fig. 3**). Depolarizing current injections evoked an increase in action potential (AP) frequency, which was significantly reduced in dVenus$^+$ neurons compared to dVenus$^-$ neurons (**Fig. 3A,B**) (current injected x treatment x cell type interaction effect: $F(75,1225)=1.93$, $p<0.0001$; saline-dVenus$^+$ vs. saline-dVenus$^-$: $p=0.04$). However, compared with saline-injected animals, corticosterone selectively increased the AP frequency elicited by depolarizing current injections in dVenus$^+$, but not in dVenus$^-$, neurons in mice that were fear conditioned (**Fig. 3A-C**) (Saline-dVenus$^+$ vs. CORT-dVenus$^+$: $p=0.26$; CORT-dVenus$^+$ vs. CORT-dVenus$^-$: $p=0.78$). In naïve home cage mice with no prior fear conditioning, the AP frequency was similarly lower in dVenus$^+$ cells compared with dVenus$^-$ cells in both groups, but corticosterone injection did not enhance AP frequency in dVenus$^+$ neurons (nor in dVenus$^-$ neurons) (**Fig. 3D,E**) (current injected x treatment x cell type interaction effect: $F(75,1700)=4.30$, $p<0.0001$; saline-dVenus$^+$ vs. saline-dVenus$^-$: $p=0.01$; saline-dVenus$^+$ vs. CORT-dVenus$^+$: $p=0.93$). Hence, corticosterone increased the excitability of activated (dVenus$^+$) DG neurons, potentially contributing to the enhanced ensemble size at 90 min and 24 h after conditioning (see **Fig. 2B-E**).

At 5 hours after training, we examined the effects of corticosterone injection on synaptic transmission by analyzing the properties of miniature excitatory postsynaptic currents (mEPSCs). We found that the frequency of mEPSCs was higher in dVenus$^+$ neurons compared to dVenus$^-$ neurons of saline injected mice (**Fig. 3F-H**) ($F(1,14)=10.9$, $p=0.005$). Compared with saline-treated mice, corticosterone injection significantly enhanced the mEPSC frequency selectively in dVenus$^-$ neurons (**Fig. 3F-H**) (interaction effect: $F(1,14)=8.05$, $p=0.01$, post-hoc: $p=0.04$), but did not alter the amplitude of mEPSCs in dVenus$^+$ and dVenus$^-$ neurons (**Fig. 3G,H**) ($F(1,14)=2.91$, $p=0.11$). The increase in frequency of mEPSCs in dVenus$^-$ neurons after corticosterone injection may reflect altered presynaptic input onto these neurons.

Chemogenetic suppression of the DG engram population reduced corticosterone-induced generalized fear

Previous studies have shown that inhibition of fear conditioning-activated DG neurons impairs memory retrieval upon re-exposure to the training context (*27*, *31*). Based on this, we next investigated whether the DG neurons activated during conditioning paired with corticosterone were responsible for the observed fear generalization in a neutral context. To assess this, we used a well-established viral-TRAP (Targeted Recombination in Activated Populations) approach, restricting expression of the inhibitory Gi-DREADD (hM4Di (*30*)) to activated neurons under control of the Fos promoter in a Cre recombinase and 4-hydroxytamoxifen (4OHT) dependent manner (*24*, *25*) (**Fig. 4A**). After training, both groups were injected with corticosterone and 2 h later received 4OHT to allow expression of hM4Di-mCherry or mCherry alone (control) in activated DG neurons (**Fig. 4B**). When mice were re-exposed to context A (without CNO) freezing levels were similar between groups **(Fig. 4C**) ($t(15)=0.64$, $p=0.53$). Thirty minutes before exposure to the neutral context B, all mice received CNO to suppress the activity of DG neurons that were tagged after training. Whereas mCherry control mice showed substantial baseline freezing in context B, suppression of hM4Di$^+$ neurons reduced freezing behavior (**Fig. 4D**) (post hoc: baseline-mCherry vs. baseline-hM4d: $p=0.0001$) to a level that that was comparable to control mice that did not receive post-training corticosterone (see **Fig. 1B**). Indeed, contextual fear generalization, quantified as the ratio of context-evoked freezing in context B (novel context) relative to freezing in context A (training context), was reduced following suppression of hM4Di$^+$ neurons in corticosterone treated mice (**Fig. 4E**) ($t(15)=3.55$, $p=0.003$). Freezing to the tone remained unaffected by CNO (**Fig. 4D**) ($F(1,30)=7.57$, $p=0.01$, post hoc tone-mCherry vs. tone-hM4Di: $p=0.66$). This confirms that inhibition of these DG neurons prevented the expression of contextual memory generalization.

Finally, we determined whether DG neurons that were tagged with viral-TRAP were reactivated upon exposure to context B, similar to what we observed in the Arc::dVenus

mice. Indeed, control mice expressing mCherry alone showed substantial reactivation of tagged neurons, whereas in mice injected with hM4Di-mCherry, c-fos expression was selectively reduced in mCherry^{+} neurons (**Fig. 4F,G**) ($F(1,30)=48.79$, $p<0.0001$, post hoc: control-mCherry^{+} vs. hM4Di-mCherry^{+}: $p<0.0001$; hM4Di-mCherry^{-} vs hM4Di-mCherry^{+}: $p=0.86$). This confirms that the neurons tagged during training were indeed reactivated during expression of fear in a neutral context. Together, these data indicate that corticosterone-induced generalized fear is driven by the increased DG engram population and that suppression of this improves contextual discrimination.

Journal Pre-proof

Discussion

A delicate balance between memory strength, specificity and generalization is essential to enable efficient encoding and retrieval of highly salient, stress-related information (*32*). We report here that corticosterone, the main glucocorticoid stress hormone in mice, alters the size of a fear memory-encoding DG engram population and that this population is functionally responsible for the expression of generalized contextual fear.

Various lines of evidence indicate that GRs are involved in enhancing memory consolidation. Our findings demonstrate that glucocorticoid hormones, via GRs, are also involved in the effects of corticosterone on memory generalization (**Fig. 1F,G**). In line with this, it was recently reported that corticosterone, at levels that activate GRs, reduces memory accuracy (*33*). Thus, activation of GRs not only enhances contextual memory consolidation, but also memory generalization, and we now show that this effect is mediated via an increase in the DG engram cell population. The presently observed contextual memory generalization in a novel context was not simply due to enhanced memory strength, since no differences were observed between saline and corticosterone injected mice in fear expression when mice were tested in the conditioning context. Additionally, the observed effects required associative learning, since corticosterone did not alter the number and excitability of activated DG neurons when mice did not receive aversive foot-shocks in the conditioning context. These two findings point toward a specific role of corticosterone in the enhancement of memory generalization.

We observed that corticosterone increased the sparse number of activated DG cells after training, as well as at 24 h after training, pointing to a stable change in the fear-encoding DG engram population. Whereas reactivation of learning-activated DG neurons upon re-exposure to the conditioned context was not affected by corticosterone treatment, we found enhanced reactivation of the same population upon exposure to a neutral context. Importantly, selective inhibition of DG neurons that are activated by fear conditioning plus elevated corticosterone levels prevented the expression of generalized contextual fear, while

leaving memory for the conditioned tone unaffected. Although we did not examine whether activity of the learning-activated DG neurons was required for memory expression upon re-exposure to the conditioning context (i.e. context A), this has previously been shown by others (27, 31) and we thus expect that this is not further affected by elevated corticosterone levels. However, we extend these earlier findings by showing here that the corticosterone-induced increase in the size of a DG engram cell population is responsible for a generalized expression of fear also in a neutral context. Our results support previous observations that memory specificity is related to the size of neuronal ensembles in the DG (*34*–*36*), but for the first time we causally demonstrate that glucocorticoid hormones have a critical role in modulating the incorporation of neurons in an engram population.

Alterations in neuronal excitability have been implicated in recruitment of neurons in a memory ensemble in the lateral amygdala (*29*, *37*) and after retrieval in the DG (*27*), possibly via regulation of potassium channels (*17*, *38*). We found that fear conditioning-activated DG neurons have lower excitability compared to non-activated neurons, independent of elevated glucocorticoid hormone levels. However, we demonstrate that glucocorticoid hormones specifically enhance excitability of dVenus$^+$ neurons after fear conditioning, while leaving excitability unaffected in the absence of aversive associative learning. The reduced excitability of the dVenus$^+$ cells that we observed in control mice after learning contrasts with enhanced excitability of dVenus$^+$ cells in the LA after fear conditioning (*37*) and with a transient increase in excitability of DG engram cells after memory retrieval (*38*). We speculate that decreased dVenus$^+$ cell excitability shortly after learning functions to protect the integrity of the information encoded in the DG engram cell population by avoiding subsequent recruitment of these neurons during a different experience shortly thereafter and thereby the linking of memories (*39*, *40*). This would be consistent with the pattern separation function of the DG (*41*). At the cellular level, the reduced excitability is likely due to a decrease in the membrane resistance in dVenus$^+$ cells (**Suppl. Fig. 3A**). What the molecular mechanism is that underlies the change in membrane

resistance is an important topic for future research, but is likely driven by post-translational modifications or trafficking of membrane channels given the rapid induction after learning (within 1 h). Changes in potassium channels may contribute to conditioning-induced reduction in excitability (*42*), because these proteins are thought to modulate the excitability of fear memory-encoding DG granule cells (*17*, *43*). As corticosterone selectively enhanced excitability of dVenus$^+$ neurons, glucocorticoid hormones may act as a switch to enhance excitability of conditioning-activated DG neurons and thereby the stable incorporation of neurons in a fear memory-encoding engram cell population.

Persistent alterations in synaptic strength in engram cells have been implicated in memory consolidation and this is crucial for subsequent memory expression (*37*, *44*). In control animals, we observed that fear conditioning elicited an increase in the mEPSC frequency specifically in activated DG neurons. This is in line with enhanced input of projections from the medial entorhinal cortex onto Fos-expressing DG neurons after fear conditioning (*45*). Although our recordings were performed on neurons that expressed dVenus driven by the Arc promoter, we found that the Arc$^+$ and Fos$^+$ population overlap to a large extend (*17*). Moreover, Fos-expressing DG neurons drive generalized fear in a neutral context (*45*), similar to what we observed with our Fos-promoter based viral-TRAP approach. We also found that glucocorticoid hormones enhanced the frequency of mEPSCs in non-activated DG neurons to the level detected in activated neurons 5 h after training. Thus, glucocorticoids seem to increase general synaptic transmission in DG neurons after training, possibly via increased input from the medial entorhinal cortex (*45*), which may contribute to aberrant processing of contextual information (*46*).

In line with our observations, it has been reported that stress elicits memory generalization and that glucocorticoid hormones impair the ability to correctly predict threat (*3*, *12*, *13*). Although some level of memory generalization is adaptive, as it allows a learned response to transfer to other relevant situations and stimuli, overgeneralization of fear is often maladaptive. Indeed, stressful learning experiences contribute to fear sensitization, resulting

in exaggerated startle responses to trauma-unrelated stimuli (*47*), particularly in relation to the contextual component of the memory trace. This impairment is similar to symptoms observed in PTSD patients, who often forget contextual peri-traumatic cues, whereas salient but irrelevant stimuli are strongly remembered. These salient cues, and other similar cues, can then induce strong fear responses in contexts that differ from the traumatic environment (*2*). Interestingly, noradrenaline, another key mediator of the stress response, has been shown to contribute to memory specificity (*48*). Potentially, a closely governed balance in the release of noradrenaline (specificity) and glucocorticoids (generalization), which have been reported to interact at the level of the neuronal structure (*49*), electrophysiological functioning (*10*, *50*) and behavior (*51*), is essential for accurate memory consolidation and retrieval.

The present study demonstrates that a transient post-learning increase in glucocorticoid hormone levels in male mice reduces memory specificity, thereby promoting fear memory generalization. We further reveal that glucocorticoids alter the size of the DG neuronal population that is activated by an aversive experience. Selectively suppressing this neuronal ensemble restores memory specificity. Given that stress-related disorders are often sex-dependent and that glucocorticoids regulate fear memory formation in a sex-dependent manner (22), further investigation is warranted regarding the role of these hormones on memory generalization in females.

Moreover, understanding how glucocorticoids modify the delicate balance between memory strength and specificity through changes in the size of the engram cell population opens novel avenues for the development of treatments for stress-related disorders that are characterized by maladaptive aversive memories. In this respect, our current findings may be particularly relevant in relation to anxiety disorder and post-traumatic stress disorder which have been linked to memory generalization and impaired pattern separation (*52*).

Acknowledgments: The authors want to thank dr. Priyanka Rao-Ruiz (CNCR, VU) for helpful discussions during the design of experiments.

Disclosures: The authors report no biomedical financial interests or potential conflicts of interest.

Author contribution: SLL, MCvdO, and HJK contributed to conception and design of the study; SLL organized the database; SLL, RJvdL, PB, NB, MM and NI conducted the experiments, SLL performed the statistical analysis; SLL wrote the first draft of the manuscript; SLL, MCvdO, PB, CPF, NI, MM, PJL and HJK contributed to manuscript revision, read and approved the submitted version.

Data availability: The datasets generated during and/or analyzed during the current study are available from the corresponding author on reasonable request.

COGNITIVE NEUROSCIENCE

Differentiating neural systems mediating the acquisition vs. expression of goal-directed and habitual behavioral control

Keywords: action–outcome, functional magnetic resonance imaging, habit formation, human, stimulus–response

Abstract

Considerable behavioral data indicate that operant actions can become habitual, as demonstrated by insensitivity to changes in the action–outcome contingency and in subjective outcome values. Notably, although several studies have investigated the neural substrates of habits, none has clearly differentiated the areas of the human brain that support habit formation from those that implement habitual control. We scanned participants with functional magnetic resonance imaging as they learned and performed an operant task in which the conditional structure of the environment encouraged either goal-directed encoding of the consequences of actions, or a habit-like mapping of actions to antecedent cues. Participants were also scanned during a subsequent assessment of insensitivity to outcome devaluation. We identified dissociable roles of the cerebellum and ventral striatum, across learning and test performance, in behavioral insensitivity to outcome devaluation. We also showed that the inferior parietal lobule (an area previously implicated in several aspects of goal-directed action selection, including the attribution of intent and awareness of agency) predicted sensitivity to outcome devaluation. Finally, we revealed a potential functional homology between the human subgenual cortex and rodent infralimbic cortex in the implementation of habitual control. In summary, our findings suggested a broad systems division, at the cortical and subcortical levels, between brain areas mediating the encoding and expression of action–outcome and stimulus–response associations.

Introduction

Habitual action selection is defined by insensitivity to changes in the causal efficacy with which actions produce rewards and to the current subjective value of those rewards (Balleine & Dickinson, 1998). Neuroscientific research on humans and rodents has demonstrated that the brain areas mediating habitual performance are dissociable from those supporting more deliberate, goal-directed, action selection (Balleine & Dickinson, 1998; Yin *et al.*, 2004, 2005; Valentin *et al.*, 2007; Tricomi *et al.*, 2009). Intriguingly, work in rodents also suggests that distinct neural substrates make specialized contributions to the development vs. deployment of habits (Killcross & Coutureau, 2003). In contrast, in humans there has been no clear differentiation between brain areas that support habit formation and those that implement habitual control. Although a couple of neuroimaging studies have demonstrated increases in neural activity concomitant with the development of habits in a posterior area of the lateral striatum (Tricomi *et al.*, 2009; Wunderlich *et al.*, 2012), the use of overtraining to induce habitual responding in these studies confounds well-trained performance with habitual control. In the current study, in order to discriminate between neural substrates supporting the acquisition vs. expression of habits, we scanned human participants with functional magnetic resonance imaging as they performed a novel instrumental task (see Task section in Materials and methods), designed to rapidly induce habitual responding without the potentially confounding process of overtraining.

Pharmacological disruptions and electrophysiological recordings of the rodent brain have strongly implicated the dorsolateral striatum in the acquisition of habits. Pre-training lesions of the dorsolateral striatum abolish habit formation (Yin *et al.*, 2004), and distinct changes in neuronal activity patterns (Jog *et al.*, 1999), including substantial decreases in firing rates (Carelli *et al.*, 1997; Tang *et al.*, 2007), have been demonstrated in this area across the development of habitual responding. In contrast, the infralimbic region of the prefrontal cortex has been suggested to support an executive control system that facilitates the expression of habits. Post-training muscimol-induced inactivation of the infralimbic cortex disrupts habitual performance (Coutureau & Killcross, 2003; Haddon & Killcross, 2011), and changes in neuronal ensemble activity patterns in this

area occur very late in training and closely track the behavioral manifestation of habitual control (Smith & Graybiel, 2013). Further evidence for the involvement of the infralimbic cortex in the expression of habits comes from studies in which optogenetic perturbation of this area disrupts well-ingrained habitual behavior (Smith *et al.*, 2012). Based on these findings in rodents, we hypothesized that human homologs of the dorsolateral striatum and infralimbic cortex would be involved in the formation and expression of habits respectively, such that behavioral insensitivity to outcome devaluation would correlate with neural activity during learning in the dorsal putamen (Carelli & West, 1991; Draganski *et al.*, 2008), but with activity during actual test performance in the subgenual cortex (Ongur & Price, 2000; Ongur *et al.*, 2003).

Materials and methods

Participants

Twenty volunteers (mean age 21.4 ± 2.63 years, range 19–28 years; 11 males) participated in the experiment. Due to technical problems (loss of power to the stimulus computer), one of the subjects was excluded, yielding a total of 19 participants. All participants were healthy and were recruited locally from the city of Dublin, Ireland. The study was approved by the Trinity College Dublin School of Psychology research ethics committee, and all participants gave informed consent. The study conformed to the guidelines set out in the 2013 World Medical Association Declaration of Helsinki.

Task

Goal-directed actions, defined by their sensitivity to changes in both action–outcome contingency and outcome value, have been proposed to depend on an internal model of the world that explicitly relates alternative actions to future environmental states (Doya *et al.*, 2002; Daw *et al.*, 2005). Consistent with this theoretical framework, data from rodent studies suggest that reliance on a goal-directed vs. habitual strategy might depend on the ease with which alternative actions can be associated with distinct outcomes; goal-directed performance appears to dominate, in spite of overtraining, when alternative actions yield distinct sensory-specific outcomes (e.g. grain vs. sucrose pellets) (Colwill & Rescorla, 1985; Holland, 2004), as well as when the rate of outcome delivery depends on the rate of responding, rather than on a particular time interval passing between successive reinforced responses (i.e. ratio vs. interval schedules of reinforcement) (Dickinson *et al.*, 1983). The current task was structured on these potential bases of behavioral control, in that external contingencies either facilitated or impeded a reliable mapping of alternative actions to distinct sensory-specific outcome states.

Participants were required to maintain the balance of a system of fluid-filled beakers (see Fig. 1A for details). As long as all beakers had sufficient fluid, system balance was maintained and randomly occurring balance checks yielded monetary reward. However, on each trial, one of the beakers would be emptied causing 'system imbalance', with balance checks resulting in monetary loss until the participant refilled the beaker by performing a particular instrumental action. The emptying of a beaker was always accompanied by the onset of one of four abstract cues. In the Stimulus–Response (S-R) condition, the identity of the presented cue determined which instrumental action would refill the emptied beaker, regardless of which of the beakers had lost its fluid. Consequently, across trials, each rewarded action was paired with a specific antecedent cue, but was decorrelated from the refilling of any particular beaker. Conversely, in a Response–Outcome (R-O) condition, each instrumental action refilled a particular beaker, regardless of which abstract cue was presented, such that identification of the relevant subgoal (e.g. refilling beaker 1), combined with knowledge about specific action–outcome contingencies (i.e. action 1 refills beaker 1), indicated which action would restore system balance. To ensure that discriminatory neural activity was not due to differences in the visual processing of abstract cues vs. beakers, a matching task was interleaved with the instrumental task (see Fig. 1B).

The persistent execution of an action after its outcome has been devalued is a defining feature of habitual performance (Adams & Dickinson, 1981; Adams, 1982). In the current study, following acquisition of the instrumental task, we devalued one of the four beakers by degrading its relationship to monetary gain, such that system balance was maintained, and continued to yield points even when the liquid in this beaker dropped below threshold. Because there was a small cost for regulating the system, attempts to refill this beaker now resulted in a net loss (see Fig. 1A and Experimental Procedure section for details). Based on the notion that failure to associate alternative actions with distinct outcome states obstructs goal-directed encoding, we predicted that the S-R condition would bolster habit formation during acquisition and bias participants towards habitual action selection, defined as responding to refill the devalued beaker, in subsequent test performance. Note that, in both conditions, distinct features of the stimulus environment can enter into S-R associations. Whereas, in the S-R condition, each rewarded action was reliably preceded by a particular arbitrary cue, rewarded actions in the R-O condition were reliably preceded by the emptying of a particular beaker. However, critically, it was only in the R-O condition that alternative actions could be associated with distinct outcome states. Consequently, we expected performance in this condition to be goal-directed.

Experimental procedure

We scanned participants as they acquired and performed the instrumental task, as well as during a subsequent devaluation test phase. Each subject participated in both the R-O and S-R condition, with conditions being run in separate, immediately consecutive, sessions (order counterbalanced across subjects) and with a novel set of four instrumental actions being used in each condition. Each condition included a response pre-training phase, learning phase, devaluation phase, and final test phase as described below. The response-training phase of the first condition was conducted outside the scanner (in a separate testing room), before participants were transferred to the scanner in which they remained throughout all subsequent stages of the experiment. Before being transferred to the scanner, participants were presented with a cover story describing the beaker system and task. They were told that they would be in one of two possible conditions (one in which each instrumental action refilled a particular beaker regardless of which cue was presented, and another in which the identity of the cue determined which of the four actions was required to refill an emptied beaker, regardless of the identity of that beaker) and that part of their task was to determine which of the two conditions they were in. The entire experiment lasted for approximately 2 h, with 1.5 h being spent in the scanner, and with approximately 60 min of active scanning during the learning phases and devaluation tests in each condition.

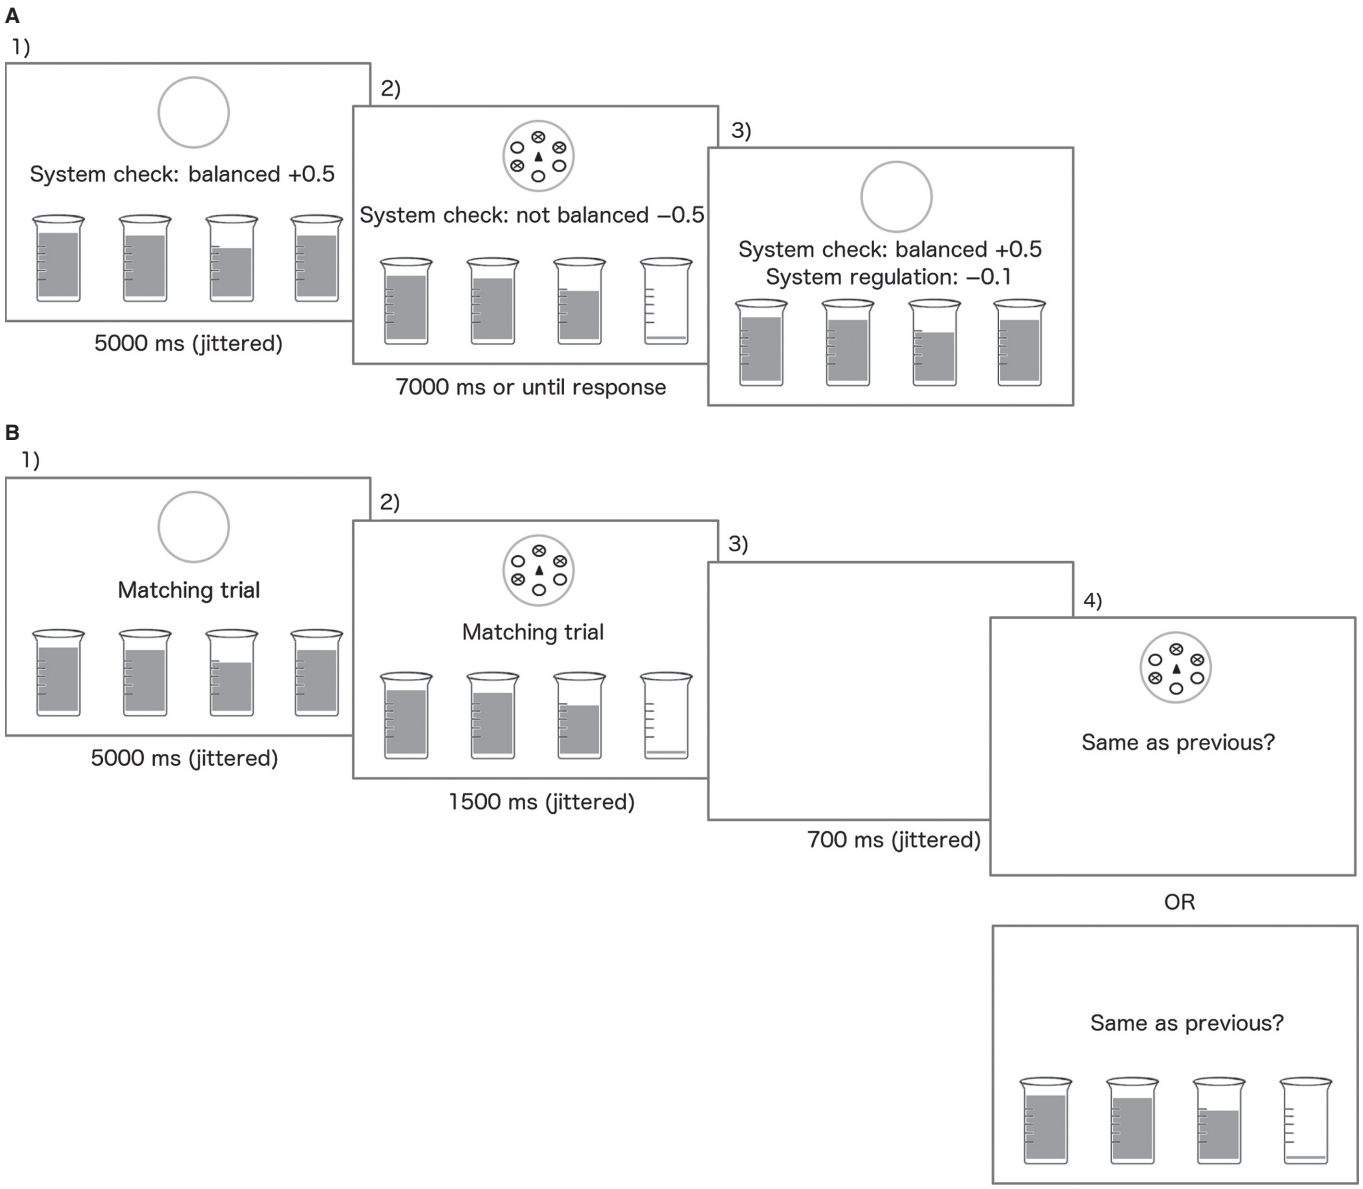

FIG. 1. Illustrations of instrumental learning and matching control tasks. (A) Instrumental learning. Participants are required to maintain the balance of a system of fluid-filled beakers using a set of four instrumental actions (each a three-press sequence, see Materials and methods). During the inter-trial interval, the liquid in the beakers continually fluctuates but remains high, and 'balance checks', occurring at brief random intervals, yield points for system balance (1). At the trial onset, one of four abstract cues appears, the liquid in one of the beakers drops to its bottom, and balance checks begin to indicate a loss of points due to system imbalance (2). Points are continually lost until the participant successfully refills the emptied beaker using one of the four actions. Following completion of the correct action (3), the abstract cue disappears, the beaker is refilled, a small fee is charged for regulating the system, and balance checks again yield points for system balance. If the correct action is not performed within 7 s, the beaker is automatically refilled, in which case there is no charge for system regulation. (B) Matching task. The inter-trial interval (1) and trial onset (2) were as in the instrumental task but were followed, at 1500 ms after trial onset, by a blank screen for 700 ms (3). The subsequent, final screen (4) showed a matching/non-matching stimulus together with a query about the match. In the S-R condition, the final screen always showed one of the abstract cues (top); conversely, in the R-O condition, the stimulus to be matched was always a set of beakers (bottom).

Response pre-training

Prior to the instrumental learning phases, participants received pre-training on the four instrumental actions (each being a three-press sequence). During this training, key-press sequences were illustrated by a white dot moving across three gray squares, horizontally aligned at the center of the screen. Initially, participants viewed and then immediately attempted to replicate each sequence, with feedback (i.e. correct/incorrect) given on each trial. After a total of five correct replications of each response sequence, they proceeded to a retrieval phase, in which they had to generate each unique sequence at least five times without any prompts, again with feedback given at the completion of each sequence. Participants were allowed to repeat these two phases as many times as they wanted to, knowing that they would have to use the actions to earn monetary reward in a subsequent phase.

Instrumental learning phase

The instrumental task was as illustrated in Fig. 1A. Note that, in addition to the increase or decrease in monetary points based on

© 2015 Federation of European Neuroscience Societies and John Wiley & Sons Ltd

system balance, there was a small cost for regulating the system. This response cost was included to ensure that, during test, participants would not respond simply based on any reinforcement intrinsic to executing the correct response. The response cost message (screen 3 in Fig. 1A) also served to inform participants that their action had successfully regulated the system, rather than the system having self-regulated (in which case no response cost was charged) due to failure to perform the correct action within 7 s of trial onset. Participants were allowed to perform as many key-presses as they wanted during system imbalance (i.e. during the 7 s following trial onset), with the correct sequence of three consecutive key-presses immediately restoring system balance and terminating the trial. There was no constraint on the temporal spacing between key-presses, as long as all three presses were performed consecutively within the trial window.

Critically, the stimulus materials presented in Fig. 1A were identical across the two conditions; our manipulation consisted entirely of differences in the contingencies between cues, actions and beaker outcomes. To rule out visual processes involved in selectively attending to the abstract cues vs. the beakers as a source of any imaging effects, a matching task was block-interleaved with the instrumental task during instrumental learning (see Fig. 1B). Briefly, in matching blocks, the inter-trial intervals and trial onsets were exactly as in the system balance task, except that the words 'Matching trial' were displayed center screen. Without this indication, matching trials would be identical to instrumental trials during the relevant trial period, and thus could not have served as controls. Following the appearance of the abstract cue and emptying of the relevant beaker, a white masking screen was displayed, followed by a depiction of either an abstract cue (S-R condition) or a set of beakers (R-O condition), together with a query about whether the currently shown cue/beaker set matched that on the previous screen. In each condition, the instrumental learning phase consisted of four blocks of trials, with each block being further divided into one sub-block of 24 instrumental trials, followed by a sub-block of eight matching trials, and with the order of trials randomized within each sub-block.

At the end of the instrumental learning phase, participants were asked whether they felt confident that they had learned how to regulate the system or whether they wanted to receive an additional set of 20 training trials (five with each action). Five participants (two in the R-O and three in the S-R condition) requested and received additional training. No scanning was conducted during additional training, nor were the added trials included in assessments of accuracy and response times during acquisition.

Devaluation phase

Following instrumental learning, participants were instructed that the system had changed such that one of the beakers was no longer relevant for system balance, which would be maintained, and continued to yield points even when the liquid in this beaker dropped below threshold. They then observed as the system regulated itself (i.e. no actions were performed) across 16 trials (four with each beaker) in order to discover the identity of the devalued beaker. Participants were told that they would not lose or gain any of the displayed points during this phase. In the imaging experiment, two participants failed to correctly identify the devalued beaker after this devaluation procedure, which was therefore repeated once for these participants. All other participants successfully identified the devalued beaker at the end of the devaluation procedure.

Test phase

Having correctly identified the devalued beaker, participants were again given the opportunity to regulate the system for personal monetary reward. During this phase, all text messages indicating gains or losses were covered up, in order to prevent additional learning (i.e. simulating extinction). Participants were instructed that, in spite of these gray strips, they should assume that all was exactly as they had learned before, i.e. they would still lose points whenever the system was not balanced, there was still a cost for regulating the system, and the previously identified irrelevant beaker was still irrelevant for system balance. Importantly, because there was a small charge for each instrumental regulation of the system, refilling the now irrelevant beaker resulted in a net monetary loss. The test phase consisted of a single instrumental block with 44 randomly ordered trials, i.e. 11 trials with each beaker, including the devalued (i.e. irrelevant) one. We operationally defined devaluation insensitivity, our assay of habitual performance, as the proportion of the 11 devalued trials on which participants initiated a response to refill the beaker. Thus, if a participant initiated a response on two of those 11 trials, their devaluation insensitivity score would be 0.18.

Pay-off structure

Throughout the instrumental task, system balance checks occurred on average every 3 s. During the inter-trial interval (mean 5 s), the system was always balanced, with each check yielding a reward of 0.5 points. At each trial onset, the system became imbalanced, with each balance check resulting in a loss of 0.5 points, and would remain so for 7 s unless regulated by the participant. Thus, if no action were taken to balance the system, each trial would entail an average loss of 1.17 points. If the system was balanced immediately, no points were lost due to system imbalance, but there was a response cost of 0.1 points (this cost was only applied to correct responses resulting in system regulation). Thus, the average gain of responding to balance the system was 1.07 points. After beaker devaluation, during the test phase, this was still the case for regulatory responses refilling non-devalued beakers; however, responding to refill the devalued beaker now resulted in a net loss of 0.1 points (the response cost).

Imaging acquisition and analyses

A 3 Tesla scanner (MAGNETOM Trio, Siemens) was used to acquire structural T1-weighted images and T2*-weighted echoplanar images (repetition time, 2.65 s; echo time, 30 ms; flip angle, 90°; 45 transverse slices; matrix, 64 × 64; field of view, 192 mm; thickness, 3 mm; slice gap, 0 mm) with blood oxygenation level-dependent contrast. To recover signal loss from dropout in the medial orbitofrontal cortex (O'Doherty *et al.*, 2002), each horizontal section was acquired at 30° to the anterior commissure–posterior commissure axis. Image processing and statistical analyses were performed using statistical parametric mapping (SPM)8 (http://www.fil.ion.ucl.ac.uk/spm). The first four volumes of images were discarded to avoid T1 equilibrium effects. All remaining volumes were corrected for differences in slice acquisition, realigned to the first volume, spatially normalized to the Montreal Neurological Institute echoplanar imaging template, and spatially smoothed with a Gaussian kernel (8 mm, full width at half-maximum). We used a high-pass filter with a cutoff of 128 s.

As previously noted, instrumental conditions were run in separate consecutive sessions, with the acquisition phase of each condition

© 2015 Federation of European Neuroscience Societies and John Wiley & Sons Ltd

consisting of interleaved instrumental and matching block, and with active scanning occurring only during the acquisition and test phase of each condition (i.e. the scanner was off during response pre-training and devaluation phases), for a total of four active scanning periods per subject. For each subject, we constructed a design matrix that included the acquisition and test phases of both experimental conditions. For each of the two instrumental acquisition phases (i.e. R-O and S-R), stick functions modeled the trial onsets in each block of instrumental learning and in matching blocks. In addition, three regressors, respectively modeling the onsets of error trials, the times of all individual key-presses and the times of all point displays (i.e. gains and losses), were entered as regressors of no interest, together with six regressors accounting for the residual effects of head motion. For each of the two test phases, two stick functions respectively modeled non-devalued and devalued trials. Again, for each instrumental condition, additional regressors modeling the onsets of error trials and the times of all key-presses were added together with six regressors accounting for the residual effects of head motion as regressors of no interest. All regressors were convolved with a canonical hemodynamic response function.

Group-level random-effects statistics were generated by entering contrasts of parameter estimates for the different regressors into between-subjects analyses of variance (ANOVAS). Specifically, to delineate neural substrates engaged during early acquisition vs. during expression, contrasts of parameter estimates for the first two blocks of instrumental learning, and for the devaluation test phase, were entered for each instrumental condition into a 2 × 2 (condition by experimental phase) ANOVA. Contrasts of parameter estimates for all learning blocks and for matching blocks were entered into a separate 2 × 2 (stimulus by task) ANOVA to compare differences between instrumental conditions during learning with those between matching control conditions. An analogous ANOVA was performed using contrasts of parameter estimates for devaluation test trials and matching trials. Finally, a 4 × 2 (acquisition block by instrumental condition) ANOVA assessed training-related changes in neural activity, with contrasts of parameter estimates for each of the four blocks of instrumental learning, for each instrumental condition. Following estimation of the second-level model, F-tests were specified by adding linear weights to each block of learning (e.g. [−1.5 −0.5 0.5 1.5] for increases across blocks and [1.5 0.5 −0.5 −1.5] for decreases) in each instrumental condition.

To assess whether neural discrimination between instrumental conditions correlated with the degree of devaluation insensitivity, a simple *t*-test was performed on first-level interaction contrasts [S-R > R-O × Instrumental > Matching] of parameter estimates from the learning phase, with the degree of devaluation insensitivity entered as a covariate. An analogous *t*-test using interaction contrasts of parameter estimates from the devaluation test phase was also performed, and exclusive functional masks were used to assess the specificity of neural effects, such that all voxels that reached significance at a threshold of $P < 0.1$ when assessing correlates of devaluation insensitivity during the test phase were removed from the effects observed during learning, and vice versa. Exclusive functional masks were also used to assess the directions of simple effects underlying the Instrumental Condition by Experimental Phase interaction. Finally, we used exclusive functional masks to selectively assess training-related increases vs. decreases in neural activity, such that, for example, when testing for increases in neural activity across blocks of training in the R-O condition, voxels were removed that reached significance at $P < 0.1$ for the same test in the S-R condition.

Small volume corrections (SVCs) were performed on several *a-priori* regions of interest using a 10 mm sphere, with center coordinates obtained from highly relevant studies. Specifically, in an analogous study on observational learning (Liljeholm *et al.*, 2012), we found selective recruitment of the extrastriate cortex (±45, −72, 9), the tail of the caudate nucleus/thalamus (±21, −30, 9) and the lingual gyrus (±12, −69, 0) by the S-R condition during acquisition. Conversely, areas selectively recruited by the R-O condition in that same observational learning study, and also identified in our other work on goal-directed performance (Liljeholm *et al.*, 2011), include the inferior parietal lobule (IPL) (±51, −52, 33) and anterior caudate nucleus (±16, 8, 19). Finally, several human neuroimaging studies have implicated a posterior region of the putamen (±33, −24, 0) in habit formation (Tricomi *et al.*, 2009; de Wit *et al.*, 2012; Wunderlich *et al.*, 2012; Lee *et al.*, 2014), and the ventromedial prefrontal cortex (±4, 55, −7) in goal-directed processes (Hampton *et al.*, 2006; Tanaka *et al.*, 2008; Liljeholm *et al.*, 2011). It should be noted that, although specified *a priori* based on a closely related literature, effects in several of these regions survived whole-brain cluster-size thresholding (CST) correction, as well as SVC, in the current study.

As noted, the putamen, considered a human homolog of the rodent dorsolateral striatum based on its afferent and efferent projections (Carelli & West, 1991; Draganski *et al.*, 2008), has been implicated in habitual performance in several human imaging studies (Tricomi *et al.*, 2009; de Wit *et al.*, 2012; Wunderlich *et al.*, 2012; Lee *et al.*, 2014). In contrast, the role of the infralimbic cortex in instrumental performance has been exclusively demonstrated in rodents (Killcross & Coutureau, 2003; Haddon & Killcross, 2011; Smith *et al.*, 2012; Smith & Graybiel, 2013). Consequently, and based on anatomical and functional evidence for a homology between the rodent infralimbic cortex and the human subgenual cortex (Ongur & Price, 2000; Ongur *et al.*, 2003; Drevets *et al.*, 2008), predictions regarding this area were tested using an anatomical mask of the subgenual cortex (Brodmann area 25), defined using the Wake Forest University Pickatlas (Maldjian *et al.*, 2003). All other effects were reported at $P < 0.05$, using CST of SPM t-maps to adjust for multiple comparisons (Forman *et al.*, 1995). AlphaSim (Ward, 2000), a Monte Carlo simulation, was used to determine cluster size and significance. Using an individual voxel probability threshold of $P = 0.005$ indicated that using a minimum cluster size of 111 Montreal Neurological Institute transformed voxels resulted in an overall significance of $P < 0.05$.

To eliminate non-independence bias for plots of contrast values, a leave-one-subject-out (Esterman *et al.*, 2010) approach was used, in which 19 general linear models were run with one subject left out in each, and with each general linear model defining the voxel cluster for the left-out subject. Using rfxplot (Glascher, 2009), mean contrast values were extracted from spheres (10 mm) centered on these leave-one-subject-out peaks (identified within regions of interest for SVCs) and were averaged across subjects to plot overall effect sizes.

Results

Behavioral results

The results from the test phase indicated that our manipulation did indeed produce differences in devaluation sensitivity. Having correctly identified the devalued beaker, participants initiated a response on a significantly greater proportion of devalued trials in the S-R condition (mean proportion 0.43, SEM 0.09) than in the R-O

© 2015 Federation of European Neuroscience Societies and John Wiley & Sons Ltd

condition (mean proportion 0.19, SEM 0.09) [$t_{18} = 2.3$, $P < 0.031$]. Indeed, whereas only five of 19 participants initiated a response on any devalued trials in the R-O condition, 15 of 19 participants initiated a response on at least one devalued trial in the S-R condition ($\chi^2 = 10.56$, $P < 0.005$).

Note that devaluation insensitivity was defined such that a response to obtain the devalued outcome (i.e. to refill the devalued beaker) was counted even if the entire three-press sequence was not completed on that trial. Indeed, in the S-R condition, when a participant responded to fill up the devalued beaker, they often did so without completing the entire three-press sequence, consistent with evidence from the rodent literature that the response most proximal to reward remains sensitive to devaluation long after more distal responses have become habitual (Killcross & Coutureau, 2003). In contrast, those few participants that responded on devalued trials in the R-O condition did so on most or all devalued trials and completed all three key-presses whenever initiating a response, suggesting a more deliberate decision to respond.

Importantly, during the test phase, whereas in the R-O condition participants could determine both the accuracy and value of a particular action solely by identifying the emptied beaker, in the S-R condition, determining the value and accuracy of a given response required identification of both the abstract cue and the emptied beaker. It is possible therefore that the differences in devaluation performance were due to this additional aspect of the S-R condition. The overall pattern of behavioral results, however, strongly suggests that this was not the case, and generally rules out task difficulty as the source of our effects. First, there were no significant differences between conditions in the percent of incorrect responses, during either acquisition [R-O: mean 14%, SEM 3; S-R: mean 11%, SEM 2; $t_{18} = 1.1$, $P = 0.30$] or test performance [R-O: mean 4%, SEM 1; S-R: mean 4%, SEM 2; $t_{18} = 0$, $P = 1.0$]. Likewise, response times did not differ between conditions during either acquisition [R-O: mean 1482 ms, SEM 62; S-R: mean 1393 ms, SEM 78; $t_{18} = 1.95$, $P = 0.21$] or test performance [R-O: mean 1258 ms, SEM 54; S-R: mean 1361 ms, SEM 68; $t_{18} = -1.52$, $P = 0.15$]. The fact that there were no significant differences between conditions in either accuracy or reaction times during test makes it highly unlikely that differences in devaluation sensitivity reflected differences in task difficulty. Perhaps most pertinently, differences in devaluation insensitivity were not correlated with differences in accuracy ($P = 0.5$) or reaction times ($P = 0.8$), nor did individual differences in accuracy or reaction times predict neural effects in any of the areas identified by our imaging analyses.

To assess the influence of counterbalancing order, we performed order-by-condition analyses of variance on response times and accuracy scores during the learning and test phases, as well as on the devaluation insensitivity scores. There was no significant interaction between order and condition for devaluation insensitivity ($F_{1,17} = 0.55$, $P = 0.47$), or for either response times ($F_{1,17} = 0.89$, $P = 0.36$) or accuracy scores ($F_{1,17} = 0.07$, $P = 0.79$) during the test phase. In contrast, during training, there was an anticipated interaction for both response times ($F_{1,17} = 5.96$, $P < 0.03$) and accuracy scores ($F_{1,17} = 23.01$, $P < 0.001$), such that response times were longer and the percent incorrect was greater for whichever condition came first. Thus, whereas the difference in response times between instrumental conditions differed across the two orders (mean difference for R-O first 0.19; mean difference for S-R first −0.32), there was no difference between instrumental conditions when compared for a given order (i.e. for R-O vs. S-R with both first, $P = 0.84$ and for R-O vs. S-R with both second, $P = 0.71$). A similar pattern was observed for percent incorrect scores (mean difference for R-O first 0.08; mean difference for S-R first −0.01; significance test for R-O vs. S-R with both first, $P = 0.26$ and for R-O vs. S-R with both second, $P = 0.90$). Consequently, we can rule out counterbalancing order as a source of our behavioral and imaging effects of interest.

There were no differences between instrumental conditions in the number of requested repetitions of response pre-training phases [R-O: mean 1.98, SEM 0.29; S-R: mean 1.75, SEM 0.18; $t_{18} = 0.72$, $P = 0.48$], or in the total number of key-presses executed during instrumental learning [R-O: mean 470.63, SEM 32.14; S-R: mean 503.74, SEM 31.63; $t_{18} = -0.85$, $P = 0.40$] or on non-devalued trials during test [R-O: mean 121.84, SEM 4.57; S-R mean: 125.53, SEM 4.53; $t_{18} = -1.34$, $P = 0.57$]. Finally, there was no difference between instrumental conditions in the total number of points earned during instrumental learning [R-O: mean 33.6, SEM 3.61; S-R: mean 33.4, SEM 3.33; $t_{18} = 0.071$, $P = 0.94$]. This allowed us to rule out the number of motor responses as well as total earnings as sources of the difference in devaluation performance.

Neuroimaging results

Our primary objective was to investigate whether neural discrimination between the two instrumental conditions differed across the acquisition and expression of behavioral control, particularly with respect to blood oxygenation level-dependent activity predictive of individual differences in devaluation insensitivity (see Table 1). To rule out the possibility that differences between our instrumental conditions were due to differences in the processing of relevant visual features (i.e. of abstract cues in the S-R condition and of the set of beakers in the R-O condition), additional analyses formally contrasted such differences with those emerging between matching control conditions (see Table 2). Unless otherwise noted, all effects reported below survived the subtraction of matching control conditions. All of the results described below survived correction for multiple comparisons at $P < 0.05$ using either whole-brain CST or SVCs based on coordinates from relevant previous studies. Notably, many of the areas specified *a priori* as targets of SVC, including the lingual gyrus, extrastriate cortex and IPL, also survived correction using whole-brain CST, as indicated in the fourth columns of Tables 1 and 2.

Discrimination between instrumental conditions during acquisition vs. performance

To delineate the neural substrates engaged during early acquisition vs. during expression of operant behavior, we entered the imaging data from the first two blocks of instrumental learning together with that from the subsequent test phase, for each instrumental condition, into a 2 × 2 (condition by experimental phase) ANOVA (see Table 1). Although processes supporting acquisition should certainly dominate during the first two blocks of instrumental learning, we cannot completely rule out the possibility that some element of expression was also present during this phase. Inclusion of only the very earliest learning trials would not eliminate this possibility, but would introduce dramatically different error levels and severely reduce the statistical power. We note, however, that the presence of processes related to expression during the early stages of instrumental learning should reduce, rather than enhance, discrimination between the levels of the 'experimental phase' variable. Thus, in areas where we did observe a significant difference in discriminatory activity across the different phases of the experiment, such differences were probably attributable to the differential effects of acquisition vs. expression.

Stimulus–Response-related activity

Activity that was greater in the S-R than the R-O condition (Fig. 2) emerged in the middle and superior occipital cortex, and in the superior parietal lobule. Interaction tests and (exclusively masked) tests of simple effects revealed that activity in the superior parietal lobule and superior occipital cortex was significantly greater in the

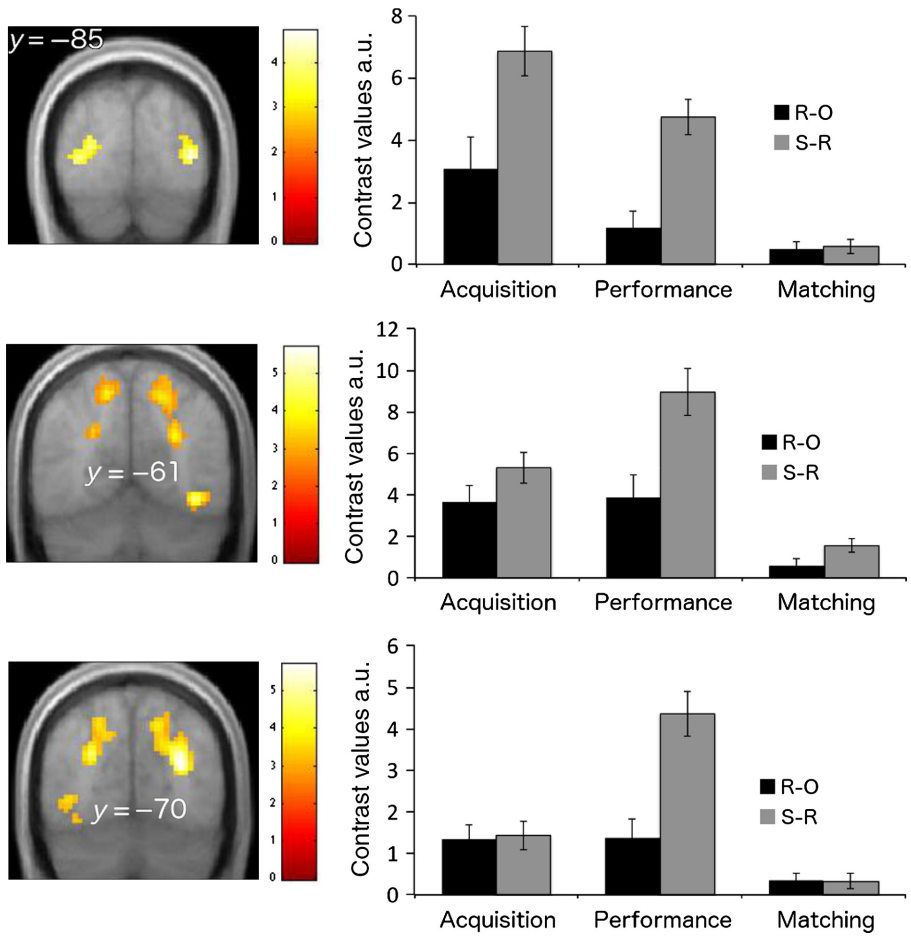

FIG. 2. Areas selectively involved in the S-R condition. Statistical maps show main effects of the S-R > R-O contrast, in the middle occipital cortex (top row), and an interaction effect {i.e. [S-R > R-O (performance > acquisition)]} in the superior occipital cortex, extending into the superior parietal lobule (middle and bottom rows). Bar plots show contrast values estimated at leave-one-subject-out coordinates for each instrumental condition, during both acquisition and performance, and for matching controls. Error bars = SEM. a.u., arbitrary units.

S-R than the R-O condition only during test performance, but not during early acquisition (Table 1). Moreover, during early acquisition, only a small area of the middle occipital cortex, the extrastriate body area (EBA; SVC), survived subtraction of corresponding matching controls (Table 2). In contrast, S-R selective activity throughout the occipital cortex, including the EBA, survived subtraction of matching controls during the test phase.

Response–Outcome-related activity

Activity significantly greater in the R-O condition than the S-R condition (Fig. 3) was observed throughout a fronto-parietal network, including the dorsal and ventral medial prefrontal cortex (VMPFC), IPLs, posterior cingulate and bilateral insula. Interaction tests and (exclusively masked) tests of simple effects revealed that, in the dorsomedial prefrontal cortex, discrimination between instrumental conditions occurred during test performance only (Table 1). Analyses assessing differences between conditions relative to matching controls also revealed R-O selective effects in the dorsal anterior caudate, but did not yield significant effects in the VMFPC (Table 2).

Discrimination between conditions across blocks of acquisition

To further assess differential activity related to acquisition processes, we tested for differences between conditions in training-dependent changes in neural activity, by adding linear weights to blocks of instrumental learning. An interaction test assessing neural activity that increased in the R-O condition and decreased in the S-R condition yielded significant effects throughout the right putamen and globus pallidus (CST, 33, −7, −5) and in the right IPL (CST, 63, −31, 37). The reverse interaction contrast, assessing neural activity that decreased in the R-O condition and increased in the S-R condition, did not reveal any significant effects. Specific assessments of increases vs. decreases revealed decreases across training blocks in the S-R condition, but not in the (exclusively masked) R-O condition, throughout the right putamen and globus pallidus (Fig. 4A). In contrast, significant increases in activity across blocks in the R-O condition, but not in the (exclusively masked) S-R condition, emerged in the right IPL (Fig. 4B).

Neural correlates of devaluation insensitivity

To relate the neuroimaging data to our behavioral effects, we tested whether neural discrimination between instrumental conditions correlated with differences between conditions in the degree of devaluation insensitivity. This was indeed the case. Participants with stronger activation of the tail of the caudate nucleus/thalamus and of the cerebellum, extending into the lingual gyrus, in the S-R relative to the R-O condition during the first two blocks of instrumental learning responded on a greater proportion of devalued trials in the

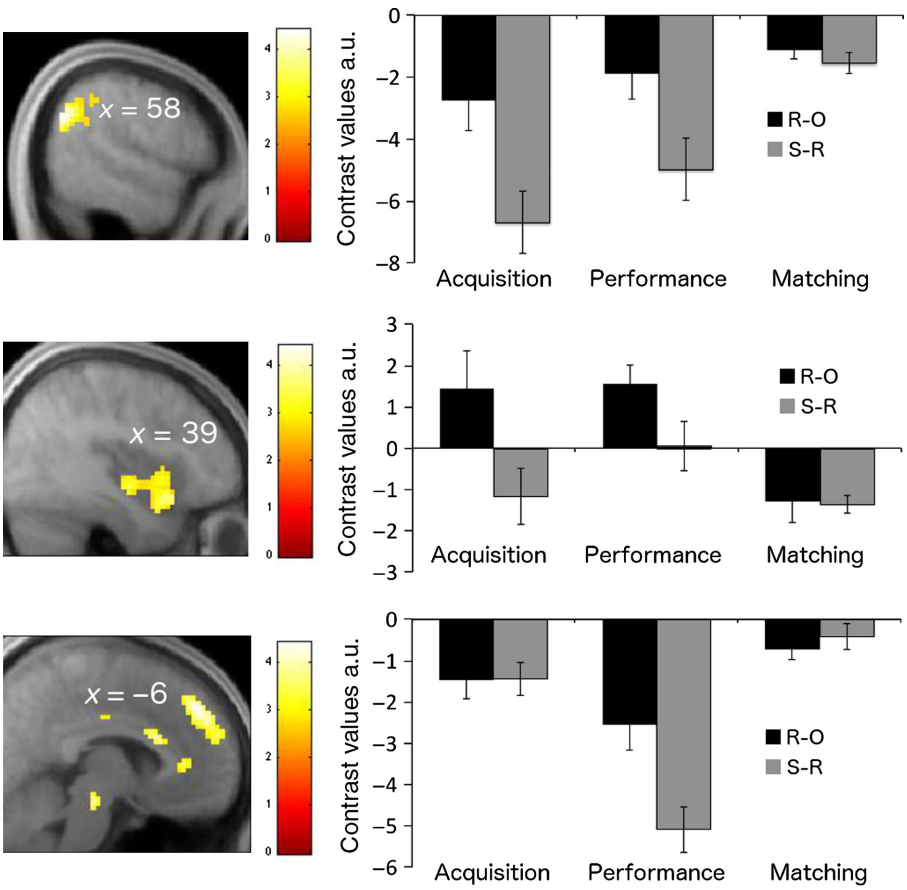

FIG. 3. Areas selectively involved in the R-O condition. Statistical maps show main effects of the R-O > S-R contrast in the posterior ventral IPL (top) and insula (middle), as well as an interaction effect {i.e. [R-O > S-R (performance > acquisition)]} in the dorsomedial prefrontal cortex (bottom). Bar plots show contrast values estimated at leave-one-subject-out coordinates for each instrumental condition, during both acquisition and performance, and for matching controls. Error bars = SEM. a.u., arbitrary units.

S-R condition relative to the R-O condition during the subsequent test phase (Fig. 5A). These effects all survived exclusive masking by an identical contrast applied, with a threshold of 0.1, to the imaging data from the test phase, suggesting that, in these areas, discriminatory activity during early acquisition, but not during test performance, predicted differences in devaluation insensitivity.

Conversely, during the test phase, differences in neural activity between the S-R and R-O conditions in the subgenual cortex (region of interest) and ventral striatum (VS) were positively correlated with the difference between conditions in devaluation insensitivity (Fig. 5B), i.e. greater subgenual and VS activity in the S-R relative to the R-O condition predicted greater devaluation insensitivity in the S-R than R-O condition. We also found a negative correlation with test performance in the right IPL (SVC), such that lesser IPL activity in the S-R relative to the R-O condition predicted greater devaluation insensitivity in the S-R than R-O condition. Again, the specificity of these results was confirmed using exclusive masking by an identical contrast, at a threshold of 0.1, applied to the imaging data from the training phase.

Discussion

In this study we explored the neural substrates of goal-directed and habitual action selection, with a focus on how the recruitment of relevant brain areas might differ across acquisition and implementation of behavioral control. We scanned human participants with functional magnetic resonance imaging as they learned and performed a novel task designed to encourage either goal-directed encoding of the specific outcomes of instrumental responses (R-O condition), or a habitual mapping of responses to antecedent cues (S-R condition). In a subsequent test phase, participants were more likely to respond for a devalued outcome, indicative of habits, in the S-R condition. We found that neural activity in striatal and cortical areas (i) discriminated between our two instrumental conditions, (ii) predicted individual differences in devaluation insensitivity and (iii) did so differentially across acquisition and test performance.

Our results identified several areas in which the degree of neural discrimination between instrumental conditions predicted differences in devaluation insensitivity. Specifically, S-R selective activity in the tail of the caudate nucleus and cerebellum during learning, but not during test performance, predicted greater devaluation insensitivity in the S-R, relative to the R-O, condition. The cerebellum has been strongly implicated in response automatization (Doyon *et al.*, 1998, 2002; Lang & Bastian, 2002; Balsters & Ramnani, 2011), a resistance to dual-task interference postulated to be closely related to, and sometimes treated as synonymous with, habitual performance. Indeed, in the rodent literature, the cerebellum has been directly implicated in habit formation, such that cerebellar lesions abolish devaluation insensitivity in overtrained rats (Callu *et al.*, 2007). However, to our knowledge, no previous study has directly linked the cerebellum to outcome devaluation insensitivity in humans. As with the cerebellum, the tail of the caudate nucleus has been

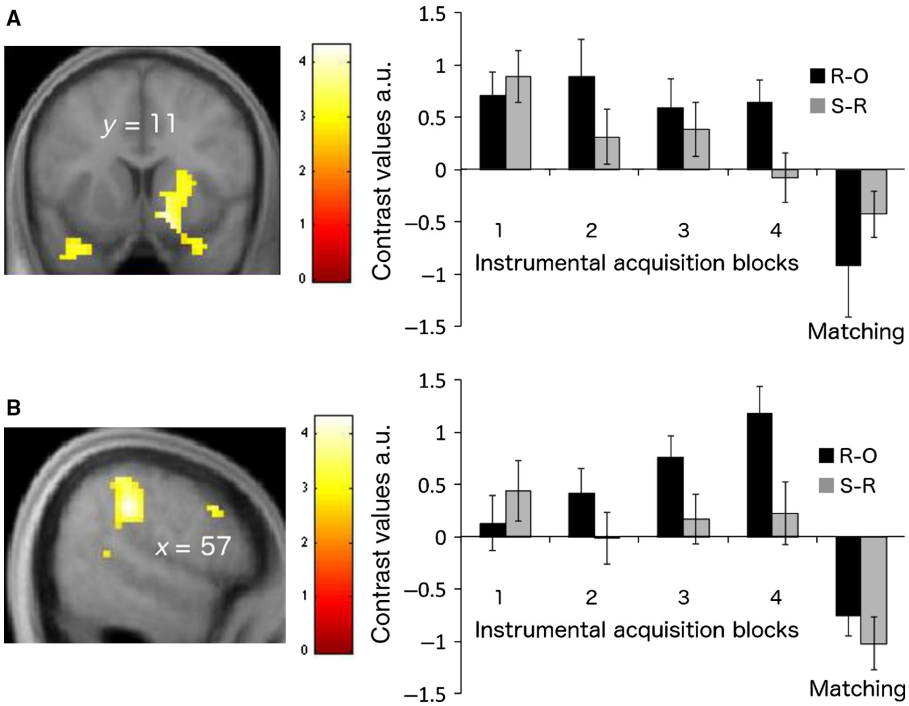

FIG. 4. Discrimination between conditions across blocks of acquisition. (A) Statistical map showing results from disjunction tests assessing decreases across blocks of acquisition in the S-R but not the R-O condition with effects emerging in the right putamen/globus pallidus. (B) Results from a disjunction test of increases across blocks in the R-O but not the S-R condition yielded effects in the IPL. Bar plots show contrast values estimated at leave-one-subject-out coordinates for each instrumental condition in each training block, as well as for matching control conditions. Error bars = SEM. a.u., arbitrary units.

implicated in skill learning (Poldrack & Gabrieli, 2001; Yamamoto *et al.*, 2013). Moreover, single neuron recordings in the monkey tail of the caudate nucleus have revealed that, relative to the body and head of the caudate, this area is specifically involved in encoding stable, non-flexible, values of visual cues (Kim & Hikosaka, 2013; Yamamoto *et al.*, 2013; Hikosaka *et al.*, 2014; Kim *et al.*, 2014), consistent with its role in devaluation insensitivity demonstrated here and elsewhere (Valentin *et al.*, 2007; Liljeholm *et al.*, 2012).

In the subgenual cingulate (Brodmann area 25), S-R selective activity during test performance, but not during learning, correlated with behavioral devaluation insensitivity. Based on its cytoarchitectonic subdivisions and connections, this area has been identified as homologous to the rodent infralimbic cortex. The rodent infralimbic and human subgenual areas both project heavily to the shell of the nucleus accumbens, and both are agranular, relatively poorly laminated areas located ventrally on the medial wall (Gabbott *et al.*, 1997; Ongur & Price, 2000; Ongur *et al.*, 2003). In rodents, the infralimbic cortex has been shown to make specialized contributions to executive control processes facilitating the deployment of habits (Coutureau & Killcross, 2003; Haddon & Killcross, 2011; Smith *et al.*, 2012; Smith & Graybiel, 2013). Consistent with such findings, our results suggest that a putative human homolog of this area does indeed play selective roles in the expression of habits. It should be noted, however, that the rodent infralimbic cortex is primarily known for its involvement in the extinction of Pavlovian responses (Milad & Quirk, 2002; Rhodes & Killcross, 2004, 2007; Santini *et al.*, 2008), whereas the human subgenual cortex has predominantly featured in studies on depression (Greicius *et al.*, 2007; Drevets *et al.*, 2008; Johansen-Berg *et al.*, 2008; Matthews *et al.*, 2009; Keedwell *et al.*, 2010). Future work is needed to reconcile these apparently divergent functions and their potential homology across species.

As with the subgenual cortex, activity in the VS during the test phase, but not during acquisition, predicted devaluation insensitivity. The VS has been frequently shown to support both the acquisition and expression of Pavlovian (stimulus–outcome) associations (Day *et al.*, 2007; Blaiss & Janak, 2009), and to mediate the general motivational influence of such associations on instrumental performance, a phenomenon referred to as Pavlovian-instrumental transfer (Corbit & Balleine, 2011). Of particular importance for interpreting the current findings is the fact that, in rodents, Pavlovian-instrumental transfer appears to selectively influence habitual, rather than goal-directed, responding, i.e. the greater the degree of insensitivity to outcome devaluation, the greater the general motivational influence of Pavlovian cues on instrumental performance (Holland, 2004; Balleine & Ostlund, 2007). We interpret the currently observed activity in the VS as reflecting a greater influence of Pavlovian cues on instrumental responding in the S-R than the R-O condition, and conjecture that this selective engagement of Pavlovian processes supported our behavioral effect.

Contrary to our predictions, we did not find a correlation between activity in the dorsal putamen during early learning and subsequent devaluation insensitivity. We did, however, find S-R selective decreases in right putamen activity across blocks of training, an effect that is consistent with a substantial literature demonstrating a decreased dependence on the putamen with extended (Ungerleider *et al.*, 2002; Poldrack *et al.*, 2005; Turner *et al.*, 2005; Ashby *et al.*, 2010), as well as intermediate (Brovelli *et al.*, 2011), levels of training. Taken together, these results suggest that the contributions of the putamen to automatic and habitual behavioral control may take place early in acquisition, with long-term storage and mediation of well-trained performance occurring elsewhere (Orban *et al.*, 2010). However, some neuroimaging studies have found increases in putamen activity with extended training (Floyer-Lea & Matthews, 2004;

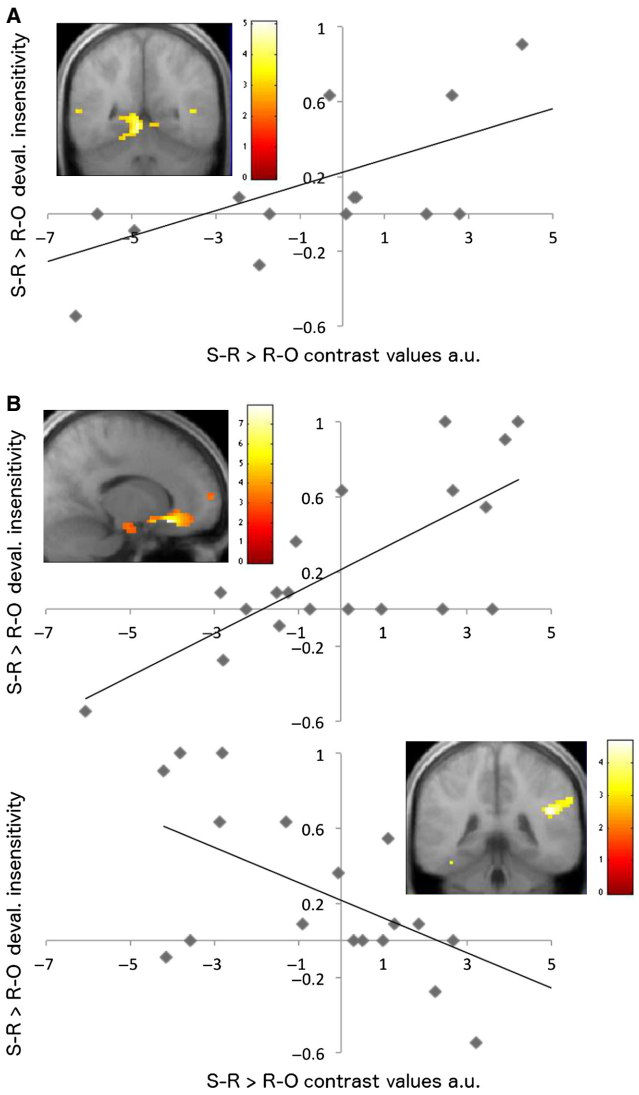

FIG. 5. Correlations between contrast values for the [S-R > R-O (instrumental > control)] contrast and behavioral differences between the S-R and R-O conditions in the proportion of devaluation insensitive responses. Contrast values are extracted from 8 mm spheres centered on the peak voxel in each area. (A) Correlation between contrast values from the first two blocks of instrumental learning (x-axis) and differences between instrumental conditions in the proportion of devaluation insensitive responses (y-axis), showing effects in the cerebellum. (B) Correlation between contrast values from the test phase (x-axis) and concurrent differences between instrumental conditions in the proportion of devaluation insensitive responses (y-axis), showing a positive correlation in the subgenual cortex (top) and a negative correlation in the right IPL (bottom).

Tricomi *et al.*, 2009; Wunderlich *et al.*, 2012). For instance, Tricomi *et al.* (2009) found an increase in activity with overtraining in a far posterior region of the right putamen, concomitant with the development of habitual performance. One key difference between the study of Tricomi *et al.* (2009) and the present one is that the S-R condition in the present study is optimized to generate the rapid acquisition and expression of habitual behavior, whereas in the study of Tricomi *et al.* (2009), behavioral expression of habits (and perhaps also acquisition) emerged much more slowly, becoming evident in behavior only after several days of training. Thus, if the involvement of the putamen in S-R learning dissipates after a period of stable habitual performance, Tricomi *et al.* (2009) may not have sampled behavior beyond that stable period, whereas our accelerated habitual learning paradigm allowed us to do so. It is also worth noting, that, whereas Tricomi *et al.* (2009) reported effects in a small area in the very far posterior putamen, our effects extend throughout the right putamen and globus pallidus.

One feature of the present results is that areas in which discriminatory neural activity was correlated with between-subject variation in devaluation insensitivity did not also show differential main effects in a comparison of S-R and R-O conditions. This may be due in part to the fact that our efforts to differentially encourage S-R and R-O learning resulted only in relative differences in devaluation insensitivity, with the majority of participants showing some degree of sensitivity even in the S-R condition. Thus, neural processes directly related to the degree of habitual responding might not be discernable in analyses that categorically compare conditions. However, not all aspects of encoding S-R associations necessarily contribute to the dominance of such associations over performance. For example, the S-R selective decreases in neural activity across blocks of acquisition, found throughout the right putamen and globus pallidus, may reflect a gradual disengagement of processes that provide critical support during the early development of S-R associations (such as the maintenance of relevant representations, the encoding of discrepancies between attempted and accurate mappings, or the retrieval of response alternatives) but that are supplanted during subsequent performance by processes mediating behavioral control.

We also found selective recruitment by the S-R condition of a lateral middle occipital area that overlaps closely with what has been termed the 'EBA' (Downing *et al.*, 2001). As the name implies, this region is known for its responses to images of human body parts, and has also been frequently implicated in action observation as well as execution (Astafiev *et al.*, 2004; Kuhn *et al.*, 2011; Liljeholm *et al.*, 2012). Notably, studies assessing the role of the EBA in action execution have employed visually guided actions, such that an arbitrary visual stimulus indicates either the location towards which a movement should be directed (Astafiev *et al.*, 2004), or which one of alternative actions should be performed (Kuhn *et al.*, 2011). It is possible therefore that this area is specifically involved in limb movements that are largely stimulus-driven. In the current study, the S-R condition was designed to encourage a mapping of responses to arbitrary antecedent visual cues by decorrelating actions from sensory-specific outcome features (and indeed from any visual features that were intrinsically related to the goal of maintaining beaker fluids). Thus, one possible explanation for the selective recruitment of EBA by the S-R condition is that this area mediates the detection and mapping of arbitrary stimuli to behavioral responses.

The VMPFC has been implicated in goal-directed performance in numerous human neuroimaging studies, and is a proposed homolog of the rodent prelimbic cortex (Balleine & O'Doherty, 2010), lesions of which disrupt the acquisition, but not the expression, of goal-directed performance (Ostlund & Balleine, 2005). Although we did find selective recruitment of the VMPFC by the R-O condition during learning, this effect did not survive the subtraction of matching control conditions. It is possible, of course, that the process supported by the VMPFC, for example assigning values to subgoals, was elicited by the relevant stimuli in the matching task as well as the instrumental task. Another possibility, given our robust effect of experimental phase in the VMPFC, such that activity was greater during early acquisition than during test in both conditions, is that the goal-directed function supported by the VMPFC was present in both instrumental conditions during early acquisition. Further work is needed to arbitrate between these possibilities.

© 2015 Federation of European Neuroscience Societies and John Wiley & Sons Ltd

Further dissociating the contributions of medial prefrontal areas, we found that activity in a more dorsal medial prefrontal region was greater in the R-O than the S-R condition during test performance, but not during early acquisition. This region, along with the adjacent dorsal anterior cingulate, has been implicated in tasks in which the attainment of goals and rewards requires high levels of cognitive control, such as when monitoring for unfavorable outcomes, and during response conflict and decision uncertainty (Ridderinkhof *et al.*, 2004a,b). The currently observed pattern of activity in this area may reflect a decrease in performance monitoring and outcome evaluation during habitual relative to goal-directed control.

In our novel task the stimulus materials were identical across S-R and R-O conditions, but the instrumental contingencies encouraged participants to attend to different visual features (cues vs. beakers). Although we used a simple match-to-sample task to rule out visual processes involved in selectively attending to such features as a source of any imaging effects, there may be aspects of visual attention that are intrinsically related to instrumental responding. For example, we found greater activity in the R-O than the S-R condition in a posterior ventral region of the IPL during both the learning and test phase; during test, discriminatory activity in this area predicted greater sensitivity to devaluation. The posterior ventral region of the IPL has been proposed to function as a 'circuit break' that redirects attention towards behaviorally relevant information that is either exogenously presented (Corbetta & Shulman, 2002; Corbetta *et al.*, 2008; Cabeza *et al.*, 2012) or retrieved into working memory (Cabeza *et al.*, 2012). Importantly, substantial evidence also indicates that the posterior ventral region of the IPL is deactivated when the new information is not relevant to the current task (Shulman *et al.*, 2003). As can be seen in Fig. 3 (top), activity in the posterior ventral region of the IPL appears to be deactivated in both instrumental conditions relevant to the matching control, but markedly more so in the S-R condition. A possible explanation for this pattern of results is that greater suppression was required in the S-R condition because the sensory features of the beaker subgoal, although ultimately irrelevant for response selection, was intimately related to the trial outcome. Indeed, this augmented suppression of sensory-specific outcome features may be a general property of S-R learning, particularly as the retrieval of such features into working memory is considered central to goal-directed encoding (Balleine & Ostlund, 2007).

Consistent with evidence from the rodent literature that goal-directed performance persists in tasks in which alternative actions produce distinct rewards (Colwill & Rescorla, 1985; Holland, 2004), we found that human action selection was more goal-directed in a condition in which instrumental actions obtained unique subgoals. Formally, the degree to which alternative actions yield distinct outcome states can be quantified as the divergence of their outcome probability distributions. In a previous study (Liljeholm *et al.*, 2013), we found that activity in the right anterior IPL (the anterior dorsal supramarginal gyrus) increased with increasing outcome divergence. Likewise, in the current study, training-dependent increases in this area were found in the R-O, but not the S-R, condition, potentially reflecting the incremental increase in divergence as actions became associated with their respective outcome states. The selective recruitment of the IPL by the R-O condition, and the correlation between such discriminatory neural activity and behavioral sensitivity to outcome devaluation, is also consistent with a large body of research implicating this area in various goal-directed processes, including the computation of instrumental contingencies (Seo *et al.*, 2009; Liljeholm *et al.*, 2011), attribution of intent (den Ouden *et al.*, 2005), awareness of agency (Farrer *et al.*, 2008), and mediation of executive function (Friedman & Goldman-Rakic, 1994). Further determination of the exact contributions of the IPL to goal-directed action selection, its role in corollary attentional processes, and in representations of outcome divergence, is an important avenue for future work.

In summary, our results are novel in several critical ways. To our knowledge, we are the first to dissociate the roles of the tail of the caudate nucleus and VS, across learning and test performance, in behavioral insensitivity to outcome devaluation. We are also the first to demonstrate that activity in the IPL, an area that has been previously implicated in several processes closely linked to goal-directed action selection, including the attribution of intent and awareness of agency, predicts sensitivity to outcome devaluation. Finally, we reveal a potential functional homology between the human subgenual and rodent infralimbic cortex in the implementation of habitual control. Taken together, our findings suggest a broad systems division, at the cortical and subcortical levels, between brain areas mediating the acquisition and expression of action–outcome and S-R associations. Notably, a fundamental issue in the search for treatments of behavioral disorders is how to both facilitate the automatization of actions that lead to healthful consequences and abolish well-established deleterious habits. An improved understanding of how distinct neural substrates in the human brain mediate the acquisition vs. expression of habitual control, the aim of the present study, is therefore of significant clinical interest.

Hippocampal Substructural Vulnerability to Sleep Disturbance and Cognitive Impairment in Patients with Chronic Primary Insomnia: Magnetic Resonance Imaging Morphometry

Eun Yeon Joo, MD, PhD[1]; Hosung Kim, PhD[2]; Sooyeon Suh, PhD[3,4]; Seung Bong Hong, MD, PhD[1]

[1]Sleep Center, Department of Neurology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Samsung Biomedical Research Institute, Seoul, Korea; [2]Department of Neurology and Brain Imaging Center, Montreal Neurological Institute and Hospital, McGill University, Montreal, Quebec, Canada; [3]Korea University Ansan Hospital, Human Genome Institute, Korea University, Seoul, Korea; [4]Stanford University, Department of Psychiatry, Redwood City, CA

Study Objectives: Despite compelling evidence from animal studies indicating hippocampal subfield-specific vulnerability to poor sleep quality and related cognitive impairment, there have been no human magnetic resonance imaging (MRI) studies investigating the relationship between hippocampal subfield volume and sleep disturbance. Our aim was to investigate the pattern of volume changes across hippocampal subfields in patients with primary insomnia relative to controls.

Design: Pointwise morphometry allowed for volume measurements of hippocampal regions on T1-weighted MRI.

Setting: University hospital.

Patients: Twenty-seven unmedicated patients (age: 51.2 ± 9.6 y) and 30 good sleepers as controls (50.4 ± 7.1 y).

Interventions: N/A.

Measurements: We compared hippocampal subfield volumes between patients and controls and correlated volume with clinical and neuropsychological features in patients.

Results: Patients exhibited bilateral atrophy across all hippocampal subfields ($P < 0.05$ corrected). Cornu ammonis (CA) 1 subfield atrophy was associated with worse sleep quality (higher Pittsburgh Sleep Quality Index and higher arousal index of polysomnography) ($r < -0.45$, $P < 0.005$). The volume of the combined region, including the dentate gyrus (DG) and CA3-4, negatively correlated with verbal memory, verbal information processing, and verbal fluency in patients ($|r| > 0.45$, $P < 0.05$). Hemispheric volume asymmetry of this region (left smaller than right) was associated with impaired verbal domain functions ($r = 0.50$, $P < 0.005$).

Conclusion: Hippocampal subfield atrophy in chronic insomnia suggests reduced neurogenesis in the dentate gyrus (DG) and neuronal loss in the cornu ammonis (CA) subfields in conditions of sleep fragmentation and related chronic stress condition. Atrophy in the CA3-4-DG region was associated with impaired cognitive functions in patients. These observations may provide insight into pathophysiological mechanisms that make patients with chronic sleep disturbance vulnerable to cognitive impairment.

Keywords: chronic insomnia, hippocampus, memory, morphometry, sleep, surface analysis

INTRODUCTION

Chronic primary insomnia, also termed psychophysiological insomnia, is a disorder characterized by chronically disturbed sleep and sleep loss, nonrefreshing sleep, and heightened arousal in bed; these symptoms have a profound effect on psychological well-being, as well as on social and cognitive functioning.[1] Patients with chronic primary insomnia commonly have daytime cognitive impairments and deficits in memory consolidation during sleep compared to good sleepers.[2,3] Negative association of disturbed sleep with performance on memory tasks[2,4,5] implicates hippocampal dysfunction in patients. The hippocampus consists of cytoarchitectonically distinctive and functionally specialized subfields,[6–8] the cornu ammonis sectors (CA1-4), the dentate gyrus (DG), and the subiculum. The hippocampus is a target for glucocorticoids and is thereby vulnerable to stress-induced responses that affect both the structure and function of the hippocampus.[9] Acute or prolonged psychosocial stress is associated with structural changes of the CA1 or CA3 neurons[10,11] as well as the DG in mammals.[12,13] Individual hippocampal subfields are responsible for distinct cognitive functions, and differentially vulnerable to neurological and neuropsychiatric conditions.[14–18] Experimental sleep deprivation and fragmentation affect neurogenesis and cell proliferation.[19,20] These studies have suggested that chronic psychological stress conditions driven by sleep fragmentation in patients with chronic insomnia may contribute to alterations in the flow of information through the hippocampal network because of an anomaly in the synaptic pathways, which is reflected by subfield-specific cytoarchitectonic damage, ultimately yielding a negative influence on cognition.[21]

Sophisticated neuroimaging techniques allow for the *in vivo* visualization of human brain anatomy with exquisite detail and the quantification of morphological changes. Recent chronic insomnia studies have analyzed hippocampal volume (HV) on magnetic resonance imaging (MRI),[22–24] but findings have been inconsistent. Although a first study observed bilaterally reduced

HV in patients compared to good sleepers,[23] two recent studies did not replicate this finding.[22,24] Moreover, our group[22] found that memory impairments in patients with chronic insomnia are related to a decrease in HV. This discrepancy may be related not only to the low sensitivity of global hippocampal volumetry, but also the variability of the hippocampal segmentation between studies.[25] So far, there has been only one study that examined the regional specificity of hippocampal changes in patients and good sleepers, which revealed no significant difference between groups.[26] The automated subfield volumetry used in the study may not have been sufficiently sensitive to visualize hippocampal subfields at a low resolution MRI (1 mm^3). Alternatively, vertex (= point)-wise morphometry based on a surface extracted from the manual segmentation of the whole hippocampus[27–29] has been a surrogate to manual subfield volumetry, which can only be done on high-field (> 3 Tesla) and high-resolution MRI.[30–33] These surface-based approaches, which generate deformation maps that encode individual local shape variation relative to the template, have successfully identified hippocampal subfield pathology in various brain disorders.[27,28,34–36]

The objective of the current study is to investigate the pattern of volume changes across hippocampal subfields in patients compared to controls. Furthermore, we assessed the relationships between subfield volumes and clinical and neuropsychological parameters in patients. To this end, we quantified local volume changes using our previously developed surface-based framework. This procedure extracts the hippocampal boundary from manual labeling using spherical mapping to guarantee intersubject point correspondence.[37] Furthermore, it computes surface-based, point-wise jacobian determinants that represent local volume changes of a given hippocampus relative to the mean shape of all healthy hippocampi.[38] Compared to conventional surface shape analyses,[23,33] our technique, derived from other approaches,[37,39] allows the measurement of actual changes in volume independent of positional changes.[38,40]

METHODS

Forty patients with complaints of sleep onset and/or maintenance insomnia were recruited from a sleep disorder clinic in a university hospital setting (Samsung Seoul Hospital) located in Seoul, South Korea. Patients included in the current study must have met the following criteria: age 40–70 y, meet diagnostic criteria for chronic primary insomnia according to the International Classification of Sleep Disorders-2,[41] and have an insomnia duration of more than 1 y.

Good sleeper controls were recruited through an advertisement in the local community. Their age, sex, and education status did not differ from the patients with chronic insomnia ($P > 0.2$). All participants underwent a comprehensive clinical interview, during which a history of medical and sleep disorders was acquired. History of psychiatric disorders was assessed using the Structured Clinical Interview for Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR).[42] All participants completed a comprehensive physical and neurological examination, overnight polysomnography (PSG), neuropsychological tests, a sleep diary for at least 2 w, and a number of questionnaires assessing sleep quality and mood status.

Exclusion criteria were: (1) controls with an average nightly sleep time of less than 7 h over the recent 2 w based on sleep diaries; (2) obstructive sleep apnea (OSA, apnea-hypopnea index greater than 5/h); 3) moderate to severe periodic limb movement during sleep (PLMS, total PLM index > 25/h); (4) circadian rhythm sleep disorder determined by sleep-wake cycles of sleep diaries; (5) hypertension, diabetes, heart disease, or respiratory diseases; (6) history of cerebrovascular disease; (7) diagnosis of other neurological (neurodegenerative diseases, epilepsy, head injury) or psychiatric diseases (psychosis, current depression); (8) alcohol or illicit drug abuse or current intake of psychoactive medications; and (9) a structural lesion on brain MRI. To avoid the possible effect of medications on the results, four patients who had a history of taking antidepressants, anxiolytics, or sleeping pills were excluded. Four patients were excluded because of definite sleep disorders confirmed by PSG; three with moderate to severe OSA (apnea-hypopnea index, 17.5–40.2/h) and one with PLMS (total index 50.1/h, movement arousal index 10.5/h). Five patients who showed diffuse brain atrophy, white matter changes, or lacunar infarctions on brain MRIs were also excluded. Twenty-seven patients and 30 controls were included in the study. Of these subjects, 17 insomnia patients and 16 good sleepers were also included in a previous study.[22] Informed consent was obtained from all participants, and the institutional review board of Samsung Seoul Hospital authorized the study protocol and design.

Overnight Polysomnography

The day before the sleep study, subjects were asked to refrain from drinking alcohol or caffeinated beverages. Sleep studies were recorded using a Remlogic (Embla Systems, Denver, CO, USA). We have previously provided a detailed description of the test procedures.[39]

Neuropsychological Assessment

Subjects underwent a battery (2.5 h) of neuropsychological tests and an individual standardized intelligence test. Neuropsychological tests assessed six broad domains: working memory (digit span test from the Wechsler Memory Scale-Revised and the Corsi Block tapping tests, forward and backward); executive functioning (Trail-Making Tests A and B and the Stroop test), verbal information processing (digit symbol test), verbal memory (Korean California Verbal Test), visual memory (Rey Complex Figure Test) and verbal fluency (controlled oral word association test). Information on the protocol of the neuropsychological assessments can be found elsewhere.[22]

Self-Report Questionnaires

The Pittsburgh Sleep Quality Index (PSQI) measures the quality and disturbances of sleep during the past month.[44] A global score greater than 5 indicates poor sleep quality.

The Insomnia Severity Index (ISI) assesses subjective symptoms of insomnia, including the degree of distress caused by this particular sleep complaint.[45] A higher score represents greater insomnia severity. Scores above 14 are generally consistent with clinical levels of insomnia.[46]

The Beck Depression Inventory-II (BDI-II) measures the severity of depressive symptoms.[47] Higher scores reflect greater levels of depressive symptoms.

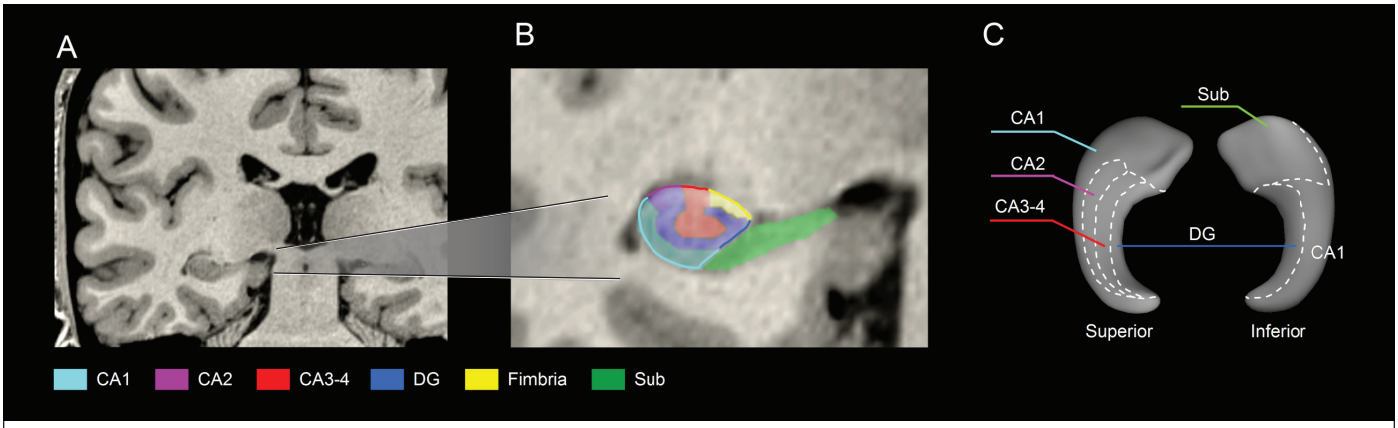

Figure 1—Surface-based subfield atlas. **(A, B)** Individual MRI on which hippocampal subfields are manually and schematically delineated based on Duvernoy atlas.[6] Our segmentation protocol excludes the subiculum at the level of hippocampal body and tail.[20] **(C)** Surface of the entire hippocampus for the same individual. By registering the given individual surface to the template representing healthy population, we obtain the borders between subfields (white dot lines) on the surface. CA, cornu ammonis; DG, dentage gyrus; Sub, subiculum

MRI Acquisition and Image Processing

MRI scanning was performed with a GE Signa 1.5-Tesla scanner (GE Medical Systems, Milwaukee, WI, USA). T1-weighted coronal spoiled gradient recalled (SPGR) MRI was performed with the following scanning variables: 1.6-mm thickness, no gap, 124 slices, repetition time (TR)/echo time (TE) = 30/7 ms, fractional anisotropy (FA) = 45°, number of excitation (NEX) = 1, matrix size = 256 × 192, and field of view = 22 × 22 cm. The voxel dimensions in the SPGR MRI images were 0.86 × 0.86 × 1.6 mm. Each image underwent automated correction for intensity nonuniformity and intensity standardization.[48]

To control for differences in brain volume, magnetic resonance images were registered into the the Montreal Neurological Institute/International Consortium of Brain Mapping standard brain template (MNI/ICBM) 152 nonlinear template[45] using a nine-parameter linear transformation.[50]

Labels of the hippocampus were obtained by manual segmentation on T1-weighted MRI according to a previous protocol[51] and used in an insomnia study,[23] which includes the DG and CA and excludes the subiculum (Figures 1A, 1B). We tested intrarater reliability on five randomly chosen control subjects. The agreement based on kappa statistics was excellent ($k = 0.94 \pm 0.02$), demonstrating that this protocol is highly reproducible.

Surface-Based Mapping of Mesiotemporal Atrophy

We used a previously validated surface-based approach[38] to measure local volume changes. This approach computes jacobian determinants on surface-based displacement vectors between a given subject and a template surface.[37] Briefly, manually segmented labels were first minimally smoothed and then converted to surface meshes for which a spherical parameterization (SPHARM) was computed using area-preserving, distortion-minimizing mapping (Figures 2A-2C). Based on a uniform icosahedron-subdivision of the SPHARM, we obtained a point distribution model (PDM), allowing shape-inherent point (1,002 vertices) correspondences across subjects (Figures 2D, 2E). Each individual SPHARM-PDM surfaces were rigidly aligned to a template constructed from the mean surface of controls and patients with respect to the centroid and the longitudinal axis of the first order ellipsoid (Figure 2E).[52] Vertexwise displacement vectors were then calculated between each individual and the template (Figure 2F).[37] Displacement vectors were diffused within the volume enclosed by the surface using a heat equation, yielding a displacement vector field. To assess local volume changes, we finally calculated jacobian determinants from these vector fields.[38] By projecting these jacobian determinants back onto the surface using trilinear interpolation and subtracting one from them, we obtained a metric of growth ($J > 0$) or shrinkage ($J < 0$) in a unit-size cube defined on each vertex (Figure 2F). We have previously shown that volume change at a vertex is driven by the structure underneath the surface.[38] Given that the surface-based analysis was performed in stereotaxic space, correction for differences in overall intracranial volume was unnecessary.

Statistical Analysis

To compare demographics, self-reported questionnaire scores, PSG data, and neuropsychological parameters between patients and controls, one-way analysis of variance was used. Six composite scores were computed from the neuropsychological tests by transforming all scores into standardized Z scores and then averaging them to represent each domain: working memory, executive functioning, verbal information processing, verbal memory, visual memory, and language processing.

Analyses to determine HV was performed using SurfStat toolbox[53] for Matlab (R2007a, The Mathworks, Natick, MA, USA). Global HV and surface-based local volumes were standardized relative to the distribution of controls using a Z-score transformation. Because no laterality of volume changes was expected in relation to insomnia,[23] we averaged the left and right volumes. In particular, local volumes were averaged at the same location between the left and right hemispheres. All the following statistical tests included BDI-II as a covariate because patients showed elevated depressive mood although this was clinically insignificant. (1) Group comparison: We compared differences in global volume between patients and controls using two-tailed *t*-tests. To assess local volume differences, we repeated the same test on vertex-wise jacobian determinants at each vertex. To assess a possible hemispheric

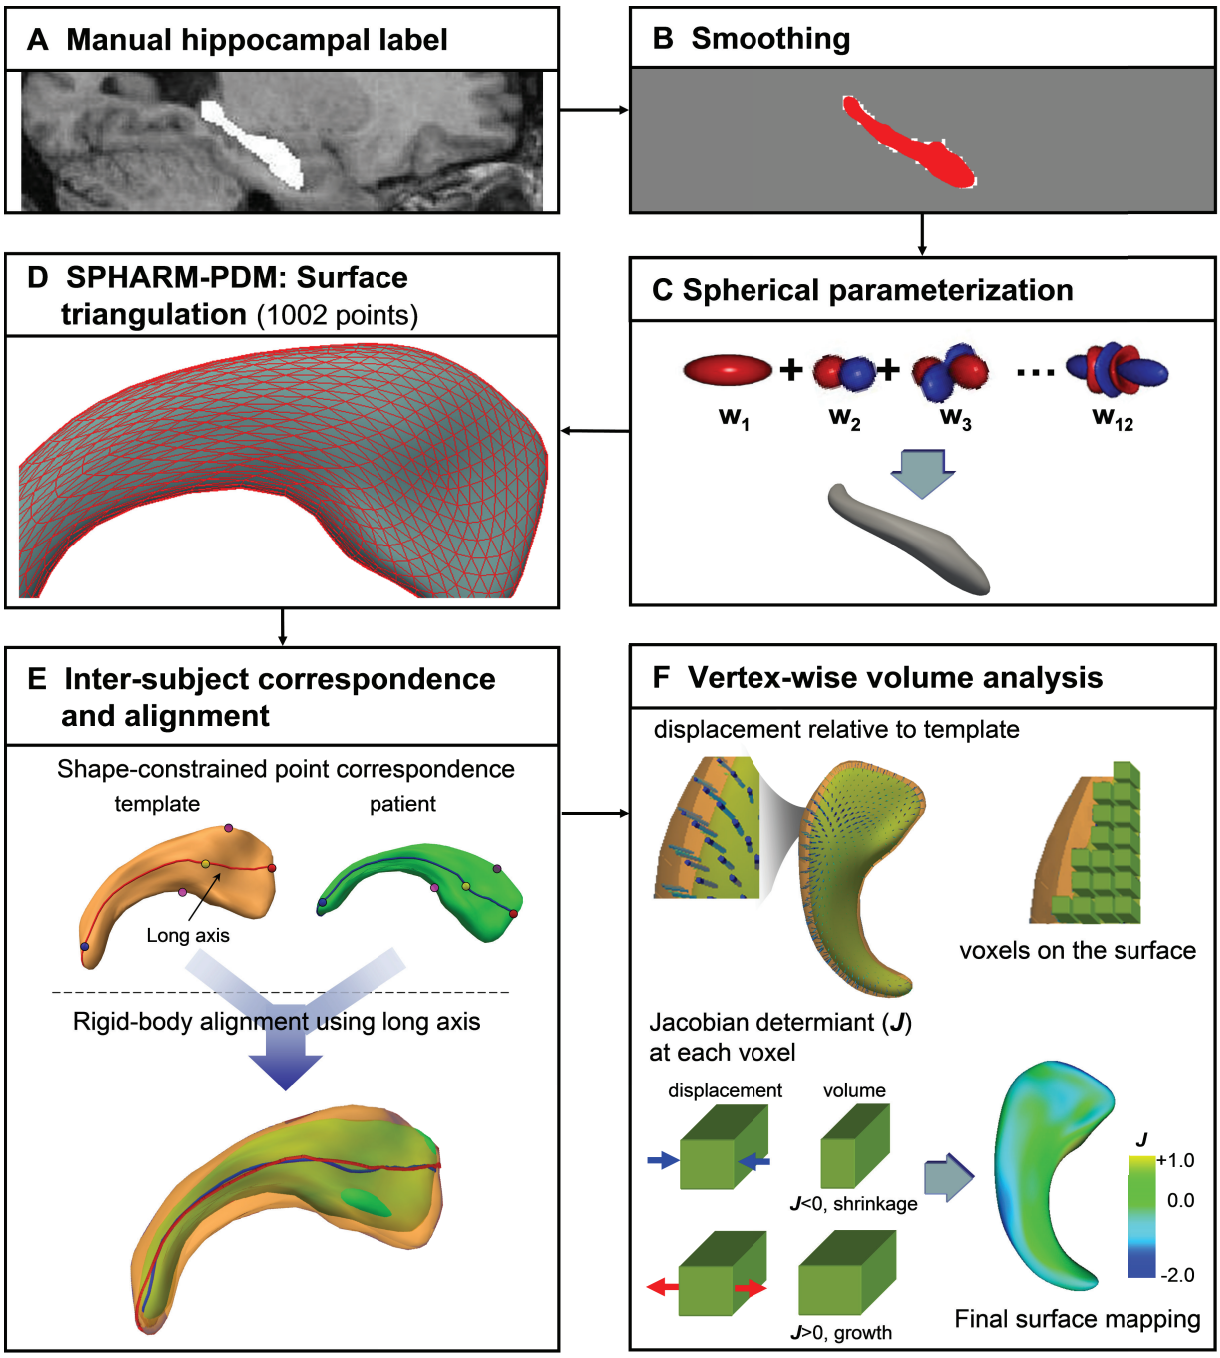

Figure 2—Flowchart of the surface-based analysis procedure. Manually segmented labels **(A)** are first minimally smoothed **(B)** and then converted to surface meshes for which a spherical parameterization (SPHARM) is computed using area-preserving, distortion-minimizing mapping **(C)**. Based on a uniform icosahedron-triangulation of the SPHARM, we obtain a point distribution model (PDM) **(D)**, allowing shape-inherent point (= vertices) correspondences across subjects **(E)** (top). Individual SPHARM-PDM surfaces are rigidly aligned to the template shape **(E)** (bottom). Vertex-wise displacement vectors are then calculated between each individual and the template **(F)** (top). Displacement vectors are diffused to voxels **(F)** (top) enclosed by the surface using a heat equation, yielding voxelwise vector field. To assess local volume changes, we calculate jacobian determinants (J) from this vector field. By projecting this metric back onto the surface using tri-linear interpolation, we finally obtain a metric of growth (J > 0) or shrinkage (J < 0) at each vertex **(F)** (bottom).

asymmetry in the changes in patients compared to controls, we first computed asymmetry in volume differences between hemispheres (i.e., 2 × (L − R) / (L + R) where L and R denote the left and right hemisphere) and further performed a *t*-test on this metric between patients and controls. (2) Reliability test: To test the reproducibility of our surface-based analysis, we performed a bootstrap analysis in which we iteratively selected random subsamples of the whole dataset (i.e., 10,000 times) and performed group comparisons at each iteration. To evaluate the consistency of patterns of volume change, we mapped the probability of having significant volume changes across all iterations on the template surface. (3) Association with clinical and neuropsychological parameters: To assess the association of volume changes with clinical demographics, PSG

and neuropsychological parameters, linear models were applied to compute Pearson correlation coefficient *r* while controlling for age, sex, and depressive mood. For local volume changes, the correlation was performed on individual measurements averaged within each significant cluster, as determined by group comparison. (4) Correction for multiple comparisons: In all vertex-wise surface analyses, significances were thresholded using the false discovery rate (FDR) procedure,[54] with FDR < 0.05. In the volumetric analysis, the Bonferroni adjustment was applied to control the family-wise error rate. (5) Localization of findings: We schematically outlined hippocampal subfields (Figure 1) on the surface template based on Duvernoy atlas[6] and its surface reconstructions that were previously published.[27,55] The segmentation protocol excluded the subiculum as the subiculum has been shown to be least affected by sleep deprivation in animal studies[19,20] and an MRI study of patients with posttraumatic stress disorder.[56] Furthermore, the one insomnia study that found significantly smaller HV among patients also excluded the subiculum.[23] We include the subiculum at the level of the hippocampal head because it was difficult to distinguish it from the hippocampus proper at our current spatial resolution. An approximate border was defined between the CA1 and DG on the inferomedial surface of the template. Although the hippocampal head contains all subfields, the portion of DG is relatively small and the DG and the CA2-4 situate in the middle.[6,57] Thus, we kept only the CA1 subfield on our surface atlas in the hippocampal head as in the previous atlases.[27,55]

Table 1—Characteristics of patients with chronic primary insomnia and controls

RESULTS

Demographics, Self-Report Questionnaires, and Overnight Sleep Studies

All subjects were right-handed. There was no difference in the mean age or sex ratio between patients and controls (P > 0.7). Subjective sleep quality was determined by the PSQI, which was assessed during the 2 w prior to the study; as expected, the mean PSQI scores were significantly higher in patients than in the controls. Patients also reported severe symptoms and had significantly higher scores on the depressive mood index compared to controls (P < 0.001), although they reported no current or lifetime psychiatric disorders during the structured clinical interview. Detailed results are summarized in Table 1.

Neuropsychological Tests

Patients had significantly lower scores in working memory, verbal information processing, verbal memory, verbal fluency, and visual memory (P < 0.0001), but not executive functioning (P = 0.6) when compared to controls. The details of neuropsychological tests are summarized in Table 2.

Global and Local Volume Changes in Patients with Chronic Insomnia Relative to Controls

A two-tailed *t*-test uncovered a significant decrease in the HV of patients versus controls (left: 2980 ± 283 versus 3197 ± 337 mm^3; right: 3079 ± 298 versus 3247 ± 404 mm^3, P < 0.05). This change was hemispherically symmetric; asymmetry between patients and controls did not differ (P > 0.2, i.e., patients presented a 3% volume difference between the left and right hippocampi and controls also presented a similar asymmetry (2%). Results of vertex-wise comparisons between groups are shown in Figure 3. In patients, hippocampal atrophy was identified in all subfields. Vertex-wise asymmetry replicated this symmetric change (FDR > 0.1). We separately mapped regional volume changes in patients

compared to controls in left and right hippocampi (Figure S1, supplemental material). This confirmed that the pattern of regional atrophy was similar between the left and right hippocampi. The largest cluster of atrophy was detected at the level of the hippocampal body and tail (FDR < 0.005, 200 vertices) and located medially, mainly within the region corresponding to the combined region of CA2-4 and DG (Figure 1A). Atrophy at the level of the head was present on the superomedial surface corresponding to CA1 (FDR < 0.05, 58 vertices). There was no local volume increase in patients relative to controls (FDR > 0.1). Bootstrap reproducibility analysis revealed that the proposed surface-based analytic platform reproduced the same patterns of atrophy in more than 85% of the random subsampling iterations (Figure S2, supplemental material).

Association Between Hippocampal Volume, and Clinical and Neuropsychological Parameters

We found that age, sex, and education did not correlate with HV in patients or controls (P > 0.2). Depressive mood (BDI-II) was associated with smaller HV (r = -0.39, P < 0.05). In patients, hippocampal atrophy were associated with worse sleep quality (PSQI) (r = -0.40, P < 0.05) and a higher arousal index on the overnight PSG (r = -0.44, P < 0.05).

Surface-based analysis revealed that the degree of volume loss in the cluster located at CA1 subfield (Figure 3A) was associated with a higher arousal index (r < -0.50, P < 0.005) as well as higher PSQI (r = -0.45, P < 0.01, Figure 3B). No significant correlations were found between surface-based volume and insomnia duration or other PSG parameters (|r| < 0.23, P > 0.2).

The atrophy of DG and CA2-4 (Figure 4A) was associated with decreased verbal memory, processing, and fluency scores (r > 0.51, P < 0.005; Figure 4C). Volume asymmetry (left smaller than right) of this area was also associated with impaired verbal processing (r = 0.50, P < 0.005).

The CA1 atrophy of the hippocampal head (Figure 4A) did not correlate with any neuropsychological parameters (r < 0.30; P > 0.1).

DISCUSSION

The current study investigated hippocampal subfield volume changes in patients with chronic primary insomnia compared to controls, and the association of specific hippocampal subfield volume differences with clinical and neuropsychological parameters.

Reduced Hippocampal Volume in Patients with Chronic Primary Insomnia

Our study uncovered bilateral atrophy across subfields in patients. Surface-based analysis revealed that this atrophy mainly corresponded to the region CA2-4-DG of the hippocampal body and tail, and CA1 subfield of the hippocampal head.

Animal studies have reported that sustained sleep fragmentation reduced neurogenesis in hippocampal subfields, particularly in the DG.[19,20] In patients with chronic insomnia, sleep fragmentation correlates with higher cortisol levels in the evening and nighttime periods.[58] The hippocampus contains a higher density of glucocorticoid receptors, which make it more vulnerable to long-term stress than most other brain areas.[59] Chronic elevations in corticosterone have been shown to suppress synaptic plasticity in the DG.[60] Chronic restraint and stress-related steroids have been shown to cause atrophy of apical dendrites of CA3 pyramidal neurons[61,62] and result in the depletion and reorganization of synaptic vesicles in mossy fiber terminals in the CA3.[61] Supporting this notion, it has been reported that patients with Cushing disease[62] and those with posttraumatic stress disorder,[63] both of whom have increased levels of cortisol, have hippocampal atrophy.

Patients in our study suffered from long-term sleep disturbances (mean 8.4 y) and their PSG findings supported evidence

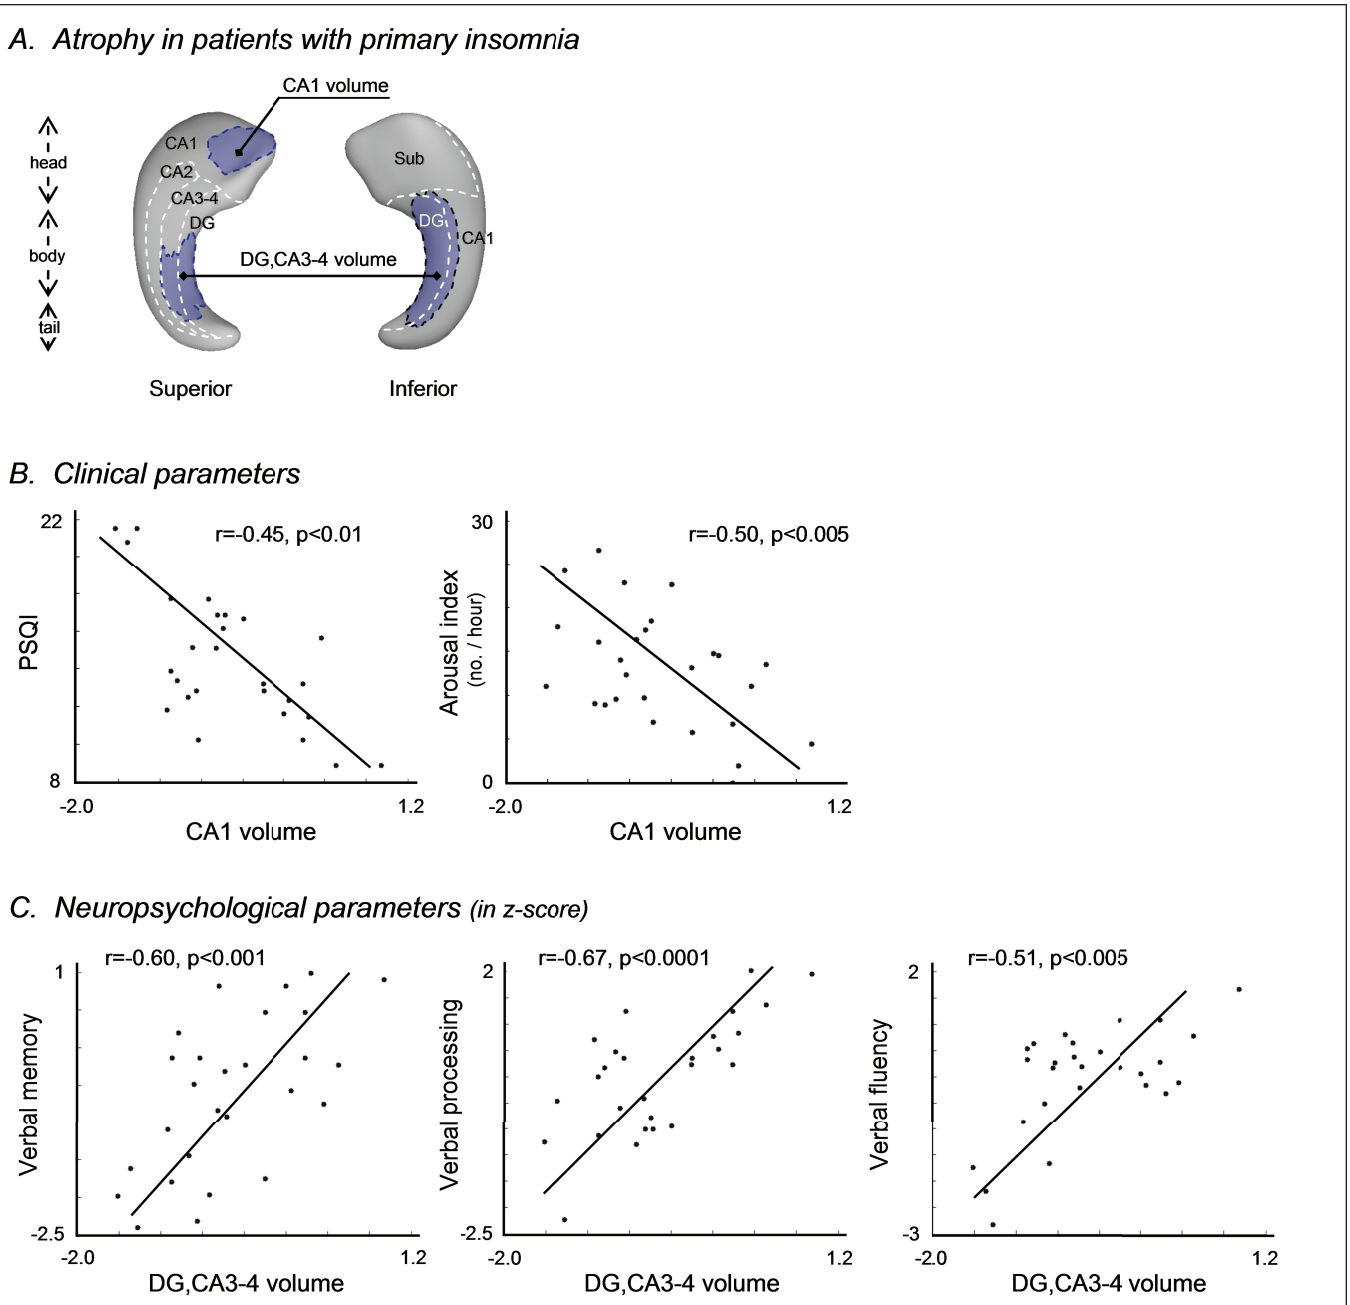

Figure 4—Association between hippocampal subfield volume and clinical **(B)** and neuropsychological **(C)** parameters in patients with chronic primary insomnia. For each cluster representing significant volume loss in patients relative to controls **(A)**, its mean volume is correlated with given clinical or neuropsychological parameter while controlling age, sex and depressive mood. Linear regression models are plotted for significant correlations. PSQI, Pittsburgh Sleep Quality Index.

of their sleep fragmentation, indexed by increased wakefulness after sleep onset, frequent arousals, and reduced sleep efficiency compared to controls. Higher arousal indices on PSG and PSQI scores were significantly associated with smaller CA1 subfield volumes in patients. It has been found that melatonin production is significantly diminished in chronic insomnia patients with sleep fragmentation.[23] Furthermore, melatonin has demonstrated protective effects in CA1 neuronal density in animal models.[64]

Our findings therefore suggest that a combined effect of disturbed sleep in patients and related chronic stress conditions may be related to the structural alteration of subfields of the hippocampal formation.

Relationship Between Hippocampal Atrophy and Cognitive Function in Patients

In the current study, patients showed cognitive impairment in verbal information processing, verbal memory, verbal processing, and visual memory compared to controls. These parameters correlated significantly with volume alterations in the cluster overlapping with the CA2-4-DG region.

The DG has been of particular interest in human cognition because dentate granule cells that are generated continuously in the adult mammalian brain[65,66] play an important role in regulating cognition[67] and storing new memories.[68] Sleep disturbance suppresses adult DG neurogenesis, especially with

on 01 February 2018

prolonged sleep disruption, which may have implications for patients with chronic insomnia who have had long-term sleep disturbance.[19,20,69,70] An MRI study that performed volumetry in patients with posttraumatic stress disorder also showed a negative correlation between insomnia symptom severity and volumes of the CA3/DG subfields.[56] It is therefore tempting to speculate that structural alterations of specific hippocampal subfields, which are secondary to prolonged sleep disruption, may lead to the impairment of cognition in patients.

The relationship between hippocampal atrophy and cognitive impairment may also be explained by a disorganization of the hippocampal circuit. The hippocampal formation is organized as a mainly unidirectional circuit made up of multiple subregions — the entorhinal cortex, the DG, the CA1 and CA3 subfields, and the subiculum.[18] These subregions differ in their cellular organization and connectivity[71] and thus, potentially make distinct contributions to the known stages of memory processing.[62,72] A previous neuroimaging study has also demonstrated that early subregions in the hippocampal circuit (DG and CA2-3) are more selectively active during episodic memory creation, whereas the next subfield in the circuit (subiculum) is more involved in the retrieval process.[73] Atrophy found in our study may be macroscopic, which is indicative of cytoarchitectonic damage in the CA2-4-DG and therefore may impair the encoding process rather than the retrieval process. This hypothesis is consistent with patients with chronic insomnia complaining of difficulties with episodic memory.[4] An MRI volumetric study of patients with subjective memory impairment confirmed that performance in memory acquisition through training is related to the volume of a combined region of CA2-4 and DG in the hippocampus.[74]

Our analysis revealed that the volume atrophy of the CA3-4-DG subfield was particularly associated with verbal-specific domains (information processing, memory, and fluency). Notably, volume asymmetry (left smaller than right) of this region in patients was also associated with impaired verbal processing. Sleep loss impedes the spontaneous generation of words during verbal word fluency tasks and the articulation of speech during vocalized reading tasks in healthy subjects[75] and patients with chronic insomnia.[76] The hippocampus is a functional network hub for memory. Information is continuously exchanged in a network of brain areas centered at the hippocampus and including the neocortex and other key structures such as the amygdala and the striatum.[77] Verbal memory is processed asymmetrically between the cerebral cortices. Encoding of verbal memory preferentially relies on left hemispheric brain regions including the hippocampus.[78] Functional MRI study have confirmed that the left hippocampus is highly activated during verbal memory tasks.[79] Moreover, the hippocampus is integrally involved in the retrieval and binding of information, critical for language processing.[80] The extent of hippocampus remaining after an anterior temporal lobectomy in patients with left mesiotemporal sclerosis was significantly related to verbal fluency after surgery.[81] Therefore, our finding that left hippocampal atrophy is related to poor performance of verbal memory and verbal fluency in patients may be explained by a pathological disruption in the brain network involved in verbal-specific domain processing.

Comparison with Other Hippocampal Volumetry Studies

Manual volumetry has been considered a standard approach to assess hippocampal structural alterations in patients with chronic insomnia. Despite a generally accepted sensitivity of this technique, because of the precise delineation of the anatomy, inconsistent reports have been published. This inconsistency may caused by variations in which substructures were included in the delineation of the hippocampus. Our study and a previous study[23] excluded the subiculum from delineation and found significantly smaller HV among patients, whereas other studies[22,24] included the subiculum and did not uncover these differences. Moreover, we studied a large sample size compared to all previous studies except one.[82] The increased significance of our results may therefore be a consequence of increased statistical power due to our large database as well as the exclusion of the subiculum, which occupies more than 20% of the HV.[32,33] The subiculum is least likely to be affected by sleep deprivation, as suggested in animal studies[19,20] and an MRI study of patients with posttraumatic stress disorder in which low sleep quality was assessed.[56]

To the best of our knowledge, our study is the first to localize HV changes in patients with primary insomnia using a surface-based analytic model. This advanced approach, relying on mesh parameterization and the use of smoothness constraints, is known to enable the localization of volume changes as small as the voxel size.[36,37,83] Indeed, our surface mapping unveils region-specific volume reductions in the hippocampus related to chronic sleep disturbance. A vertex-wise correlation of subfield volumes with clinical and neuropsychological parameters allows us to find relationships among structural changes, insomnia severity, and cognitive impairments. However, our technique has a limitation in that it differs from manual hippocampal subfield volumetry.[30–33] It is difficult to distinguish subfields at the current image resolution (1 mm^3), thus we adopted a pointwise analytic platform and interpreted changes in patients by corresponding them to a schematic atlas of the subfields based on a histology study[6] as well as previously published surface-based atlases.[27,55] The localization of atrophy to subfields in patients was thus approximate.

CONCLUSION

Our study provides evidence of disturbed sleep in patients with primary insomnia affecting the hippocampal substructure. Our primary findings indicate that patients exhibit bilateral atrophy corresponding to the CA2–4-DG of the hippocampal body and tail and CA1 of the hippocampal head. A decrease in sleep quality was closely related to the degree of hippocampal CA1 atrophy. Furthermore, atrophy located in the CA2-4-DG region was associated with impaired cognitive functions in patients with PI. These observations may provide insight into the pathophysiological mechanisms that make patients with chronic sleep disturbances vulnerable to cognitive impairment.

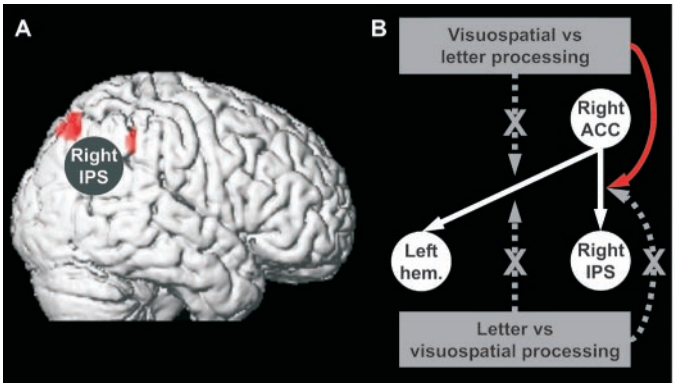

Fig. 4. PPI of the right ACC. (**A**) All areas are shown that receive a significant context-dependent contribution from right ACC during visuospatial decisions, projected on the same rendered brain as in Fig. 1. Right ACC significantly increased its influence on posterior (28/–72/48, $t_{max} = 4.49$, $P < 0.015$, corrected) and anterior parts of the right IPS (42/–42/44, $t_{max} = 4.63$, $P < 0.034$, corrected) during visuospatial decisions. Note the specificity of this result: Even when the threshold was reduced to $P < 0.05$, uncorrected, no other significant clusters were found throughout the brain. (**B**) This schema summarizes the negative findings for right ACC: As indicated by the gray dashed lines, right ACC shows no context-dependent contributions to any left-hemispheric area during visuospatial decisions and none to any left- or right-hemispheric area at all during letter decisions.

tivity (*25*) that investigated two tasks with right hemisphere dominance demonstrated top-down effects that were specific for the right hemisphere, i.e., from the right middle frontal gyrus (area 46) on right extrastriate areas. It is thus likely that our findings generalize to other lateralized tasks. Although we cannot exclude lateralization contingent on stimulus type in some situations, our results are consistent with previous findings from split-brain patient studies (*7*) and positron emission tomography (*11*) showing hemispheric specialization based on task demands. Research on hemispheric specialization should move beyond analyses of asymmetric regional activations and focus more strongly on functional interactions within and between hemispheres.

Influence of Life Stress on Depression: Moderation by a Polymorphism in the 5-HTT Gene

Avshalom Caspi,[1,2] Karen Sugden,[1] Terrie E. Moffitt,[1,2]* Alan Taylor,[1] Ian W. Craig,[1] HonaLee Harrington,[2] Joseph McClay,[1] Jonathan Mill,[1] Judy Martin,[3] Antony Braithwaite,[4] Richie Poulton[3]

In a prospective-longitudinal study of a representative birth cohort, we tested why stressful experiences lead to depression in some people but not in others. A functional polymorphism in the promoter region of the serotonin transporter (5-HTT) gene was found to moderate the influence of stressful life events on depression. Individuals with one or two copies of the short allele of the 5-HTT promoter polymorphism exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events than individuals homozygous for the long allele. This epidemiological study thus provides evidence of a gene-by-environment interaction, in which an individual's response to environmental insults is moderated by his or her genetic makeup.

Depression is among the top five leading causes of disability and disease burden throughout the world (*1*). Across the life span, stressful life events that involve threat, loss, humiliation, or defeat influence the onset and course of depression (*2–5*). However, not all people who encounter a stressful life experience succumb to its depressogenic effect. Diathesis-stress theories of depression predict that individuals' sensitivity to stressful events depends on their genetic makeup (*6*, *7*). Behavioral genetics research supports this prediction, documenting that the risk of depression after a stressful event is elevated among people who are at high genetic risk and diminished among those at low genetic risk (*8*). However, whether specific genes exacerbate or buffer the effect of stressful life events on depression is unknown. In this study, a functional polymorphism in the pro-

moter region of the serotonin transporter gene (*SLC6A4*) was used to characterize genetic vulnerability to depression and to test whether 5-HTT gene variation moderates the influence of life stress on depression.

The serotonin system provides a logical source of candidate genes for depression, because this system is the target of selective serotonin reuptake–inhibitor drugs that are effective in treating depression (*9*). The serotonin transporter has received particular attention because it is involved in the reuptake of serotonin at brain synapses (*10*). The promoter activity of the 5-HTT gene, located on 17q11.2, is modified by sequence elements within the proximal 5′ regulatory region, designated the 5-HTT gene-linked polymorphic region (5-HTTLPR). The short ("s") allele in the 5-HTTLPR is associated with lower transcriptional efficiency of the promoter compared with the long ("l") allele (*11*).

Evidence for an association between the short promoter variant and depression is inconclusive (*12*). Although the 5-HTT gene may not be directly associated with depression, it could moderate the serotonergic response to stress. Three lines of experimental research suggest this hypothesis of a gene-by-environment (G × E) interaction. First, in mice with disrupted 5-HTT, homozygous and heterozygous (5-HTT –/– and +/–) strains exhibited more fearful behavior and greater increases in the stress hormone (plasma) adrenocorticotropin in response to stress compared to homozygous (5-HTT +/+) controls, but in the absence of stress no differences related to genotype were observed (*13*). Second, in rhesus macaques, whose length variation of the 5-HTTLPR is analogous to that of humans, the short allele is associated with decreased serotonergic function [lower cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid concentrations] among monkeys reared in stressful conditions but not among normally reared monkeys (*14*). Third, human neuroimaging research suggests that the stress response is mediated by variations in the 5-HTTLPR. Humans with one or two copies of the s allele exhibit greater amygdala neuronal activity to fearful stimuli compared to individuals homozygous for the l allele (*15*). Taken together, these findings suggest the hypothesis that variations in the 5-HTT gene moderate psychopathological reactions to stressful experiences.

We tested this G × E hypothesis among members of the Dunedin Multidisciplinary Health and Development Study (*16*). This representative birth cohort of 1037 children (52% male) has been assessed at ages 3, 5, 7, 9, 11, 13, 15, 18, and 21 and was virtually intact (96%) at the age of 26 years. A total of 847 Caucasian non-Maori study members, without stratification confounds, were divided into three groups on the basis of their 5-HTTLPR genotype (*11*): those with two copies of the s allele (s/s homozygotes; n = 147; 17%), those with one copy of the s allele (s/l heterozygotes; n = 435; 51%), and those with two copies of the l allele (l/l homozygotes; n = 265; 31%). There was no difference in genotype frequencies between the sexes [$\chi^2(2) = 0.02$, $P = 0.99$]. Stressful life events occurring after the 21st birthday and before the 26th birthday were assessed with the aid of a life-history calendar (*17*), a highly reliable method for ascertaining life-event histories (*18*). The 14 events included employment, financial, housing, health, and relationship stressors. Thirty percent of the study members experienced no stressful life events; 25% experienced one event; 20%, two events; 11%, three events; and 15%, four or more events. There were no significant differences between the three genotype groups in the number of life events they experienced, $F(2,846) = 0.56$, $P = 0.59$, suggesting that 5-HTTLPR genotype did not influence exposure to stressful life events.

Study members were assessed for past-year depression at age 26 with the use of the Diagnostic Interview Schedule (*19*), which yields a quantitative measure of depressive symptoms and a categorical diagnosis of a major depressive episode according to *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria (*20*). 17% of study members (58% female versus 42% male; odds ratio = 1.6; 95% confidence interval from 1.1 to 2.2) met criteria for a past-year major depressive episode, which is comparable to age and sex prevalence rates observed in U.S. epidemiological studies (*21*). In addition, 3% of the study members reported past-year suicide attempts or recurrent thoughts about suicide in the context of a depressive episode. We also collected informant reports about symptoms of depression for 96% of study members at age 26 by mailing a brief questionnaire to persons nominated by each study member as "someone who knows you well."

We used a moderated regression framework (*22*), with sex as a covariate, to test the association between depression and (i) 5-HTTLPR genotype, (ii) stressful life events, and (iii) their interaction (table S1). The interaction between 5-HTTLPR and life events showed that the effect of life events on self-reports of depression symptoms at age 26 was significantly stronger ($P = 0.02$) among individuals carrying an s allele than among l/l homozygotes (Fig. 1A). We further tested whether life events could predict within-individual increases in depression symptoms over time among individuals with an s allele by statistically controlling for the baseline number of depressive symptoms they had before the life events occurred (table S1). The significant interaction ($P = 0.05$) showed that individuals carrying an s allele whose life events occurred after their 21st birthday experienced increases in depressive symptoms from the age of 21 to 26 years ($b = 1.55$, SE = 0.66, $t = 2.35$, $P = 0.02$ among s/s homozygotes and $b = 1.25$, SE = 0.34, $t = 3.66$, $P < 0.001$ among s/l heterozygotes) whereas l/l homozygotes did not ($b = 0.17$, SE = 0.41, $t = 0.41$, $P = 0.68$).

The G × E interaction also showed that stressful life events predicted a diagnosis of major depression among carriers of an s allele but not among l/l homozygotes ($P = 0.056$, Fig. 1B). We further tested whether life events could predict the onset of new diagnosed depression among carriers of an s allele (table S1). We excluded from analysis study members who were diagnosed with depression before age 21. The significant interaction ($P = 0.02$) showed that life events occurring after their 21st birthdays predicted depression at age 26 among carriers of an s allele who did not have a prior history of depression ($b = 0.79$, SE = 0.25, $z = 3.16$, $P = 0.002$ among s/s homozygotes and $b = 0.41$, SE = 0.12, $z = 3.29$, $P = 0.001$ among s/l heterozygotes) but did not predict onset of new depression among l/l homozygotes ($b = 0.08$, SE = 0.20, $z = 0.42$, $P = 0.67$). Further analyses showed that stressful life events predicted suicide ideation or attempt among individuals carrying an s allele but not among l/l homozygotes ($P = 0.05$, Fig. 1C). The hypothesized G × E interaction was also significant when we predicted informant reports of age-26 depression ($P < 0.01$), an analysis that ruled out the possibility of self-report bias (Fig. 1D). The interaction showed that the effect of life events on informant reports of depression was stronger among individuals carrying an s allele than among l/l homozygotes. These analyses attest that the 5-HTT gene interacts with life events to predict depression symptoms, an increase in symptoms, depression diagnoses, new-onset diagnoses, suicidality, and an informant's report of depressed behavior.

This evidence that 5-HTTLPR variation moderates the effect of life events on depression does not constitute unambiguous evidence of a G × E interaction, because exposure to life events may be influenced by genetic factors; if individuals have a heritable tendency to enter situations where they encounter stressful life events, these events may simply be a genetically saturated marker (*23*, *24*). Thus, what we have identified as a gene × environment interaction predicting depression could actually reflect a gene × "gene" interaction between the 5-HTTLPR and other genes we did not measure. We reasoned that, if our measure of life events represents merely genetic risk, then life events would interact with 5-HTTLPR even if they occurred after the depression episode. However, if our measure of life events represents environmental stress, then the timing of life events relative to depression must follow cause-effect order and life events that

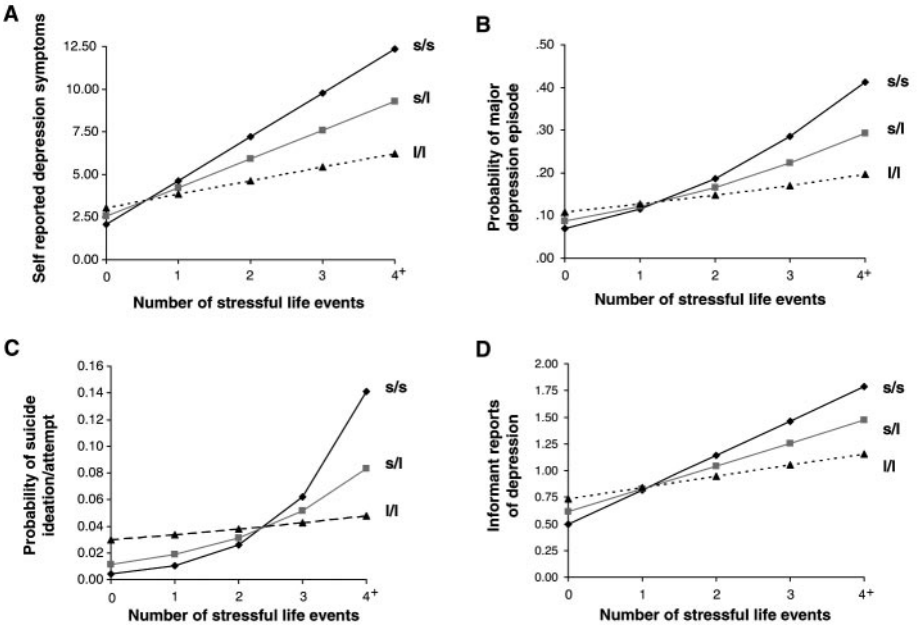

Fig. 1. Results of multiple regression analyses estimating the association between number of stressful life events (between ages 21 and 26 years) and depression outcomes at age 26 as a function of 5-HTT genotype. Among the 146 s/s homozygotes, 43 (29%), 37 (25%), 28 (19%), 15 (10%), and 23 (16%) study members experienced zero, one, two, three, and four or more stressful events, respectively. Among the 435 s/l heterozygotes, 141 (32%), 101 (23%), 76 (17%), 49 (11%), and 68 (16%) experienced zero, one, two, three, and four or more stressful events. Among the 264 l/l homozygotes, 79 (29%), 73 (28%), 57 (21%), 26 (10%), and 29 (11%) experienced zero, one, two, three, and four or more stressful events. (**A**) Self-reports of depression symptoms. The main effect of 5-HTTLPR (i.e., an effect not conditional on other variables) was marginally significant ($b = -0.96$, SE = 0.52, $t = 1.86$, $P = 0.06$), the main effect of stressful life events was significant ($b = 1.75$, SE = 0.23, $t = 7.45$, $P < 0.001$), and the interaction between 5-HTTLPR and life events was in the predicted direction ($b = -0.89$, SE = 0.37, $t = 2.39$, $P = 0.02$). The interaction showed that the effect of life events on self-reports of depression symptoms was stronger among individuals carrying an s allele ($b = 2.52$, SE = 0.66, $t = 3.82$, $P < 0.001$ among s/s homozygotes, and $b = 1.71$, SE = 0.34, $t = 5.02$, $P < 0.001$ among s/l heterozygotes) than among l/l homozygotes ($b = 0.77$, SE = 0.43, $t = 1.79$, $P = 0.08$). (**B**) Probability of major depressive episode. The main effect of 5-HTTLPR was not significant ($b = -0.15$, SE = 0.14, $z = 1.07$, $P = 0.29$), the main effect of life events was significant ($b = 0.37$, SE = 0.06, $z = 5.99$, $P < 0.001$), and the G × E was in the predicted direction ($b = -0.19$, SE = 0.10, $z = 1.91$, $P = 0.056$). Life events predicted a diagnosis of major depression among s carriers ($b = 0.52$, SE = 0.16, $z = 3.28$, $P = 0.001$ among s/s homozygotes, and $b = 0.39$, SE = 0.09, $z = 4.24$, $P < 0.001$ among s/l heterozygotes) but not among l/l homozygotes ($b = 0.16$, SE = 0.13, $z = 1.18$, $P = 0.24$). (**C**) Probability of suicide ideation or attempt. The main effect of 5-HTTLPR was not significant ($b = -0.01$, SE = 0.28, $z = 0.01$, $P = 0.99$), the main effect of life events was significant ($b = 0.51$, SE = 0.13, $z = 3.96$, $P < 0.001$), and the G × E interaction was in the predicted direction ($b = -0.39$, SE = 0.20, $t = 1.95$, $P = 0.051$). Life events predicted suicide ideation or attempt among s carriers ($b = 0.48$, SE = 0.29, $z = 1.67$, $P = 0.09$ among s/s homozygotes, and $b = 0.91$, SE = 0.25, $z = 3.58$, $P < 0.001$ among s/l heterozygotes) but not among l/l homozygotes ($b = 0.13$, SE = 0.26, $z = 0.49$, $P = 0.62$). (**D**) Informant reports of depression. The main effect of 5-HTTLPR was not significant (b = −0.06, SE = 0.06, t = 0.98, $P = 0.33$), the main effect of life events was significant ($b = 0.23$, SE = 0.03, $t = 8.47$, $P < 0.001$), and the G × E was in the predicted direction ($b = -0.11$, SE = 0.04, $t = 2.54$, $P < 0.01$). The effect of life events on depression was stronger among s carriers ($b = 0.39$, SE = 0.07, $t = 5.23$, $P < 0.001$ among s/s homozygotes, and $b = 0.17$, SE = 0.04, $t = 4.51$, $P < 0.001$ among s/l heterozygotes) than among l/l homozygotes ($b = 0.14$, SE = 0.05, $t = 2.69$, $P < 0.01$).

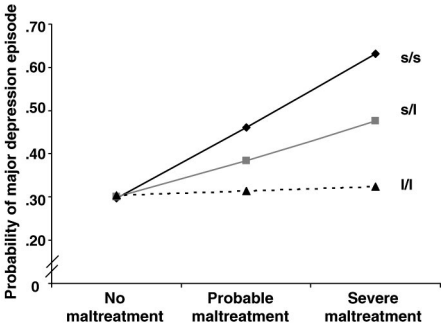

Fig. 2. Results of regression analysis estimating the association between childhood maltreatment (between the ages of 3 and 11 years) and adult depression (ages 18 to 26), as a function of 5-HTT genotype. Among the 147 s/s homozygotes, 92 (63%), 39 (27%), and 16 (11%) study members were in the no maltreatment, probable maltreatment, and severe maltreatment groups, respectively. Among the 435 s/l heterozygotes, 286 (66%), 116 (27%), and 33 (8%) were in the no, probable, and severe maltreatment groups. Among the 265 l/l homozygotes, 172 (65%), 69 (26%), and 24 (9%) were in the no, probable, and severe maltreatment groups. The main effect of 5-HTTLPR was not significant ($b = -0.14$, SE = 0.11, $z = 1.33$, $P = 0.19$), the main effect of childhood maltreatment was significant ($b = 0.30$, SE = 0.10, $z = 3.04$, $P = 0.002$), and the G × E interaction was in the predicted direction ($b = -0.33$, SE = 0.16, $z = 2.01$, $P = 0.05$). The interaction showed that childhood stress predicted adult depression only among individuals carrying an s allele ($b = 0.60$, SE = 0.26, $z = 2.31$, $P = 0.02$ among s/s homozygotes, and $b = 0.45$, SE = 0.16, $z = 2.83$, $P = 0.01$ among s/l heterozyotes) and not among l/l homozygotes ($b = -0.01$, SE = 0.21, $z = 0.01$, $P = 0.99$).

occur after depression should not interact with 5-HTTLPR to postdict depression. We tested this hypothesis by substituting the age-26 measure of depression with depression assessed in this longitudinal study when study members were 21 and 18 years old, before the occurrence of the measured life events between the ages of 21 and 26 years. Whereas the 5-HTTLPR × life events interaction predicted depression at the age of 26 years, this same interaction did not postdict depression reported at age 21 nor at the age of 18 years (table S2), indicating our finding is a true G × E interaction.

If 5-HTT genotype moderates the depressogenic influence of stressful life events, it should moderate the effect of life events that occurred not just in adulthood but also of stressful experiences that occurred in earlier developmental periods. Based on this hypothesis, we tested whether adult depression was predicted by the interaction between 5-HTTLPR and childhood maltreatment that occurred during the first decade of life (*16*, *25*). Consistent with the G × E hypothesis, the longitudinal prediction from childhood maltreatment to adult depression was significantly moderated by 5-HTTLPR (table S3). The interaction showed ($P = 0.05$) that childhood maltreatment predicted adult depression only among individuals carrying an s allele but not among l/l homozygotes (Fig. 2).

We previously showed that variations in the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) moderate children's sensitivity to maltreatment (*25*). MAOA has high affinity for 5-HTT, raising the possibility that the protective effect of the l/l allele on psychiatric morbidity is further augmented by the presence of a genotype conferring high MAOA activity (*13*, *26*). However, we found that the moderation of life stress on depression was specific to a polymorphism in the 5-HTT gene, because this effect was observed regardless of the individual's MAOA gene status (tables S4 and S5).

Until this study's findings are replicated, speculation about clinical implications is pre-

Downloaded from www.sciencemag.org on January 13, 2013

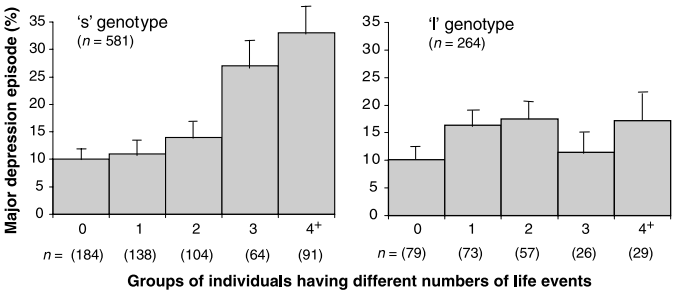

Fig. 3. The percentage of individuals meeting diagnostic criteria for depression at age 26, as a function of 5-HTT genotype and number of stressful life events between the ages of 21 and 26. The figure shows individuals with either one or two copies of the short allele (**left**) and individuals homozygous for the long allele (**right**). In a hierarchical logistic regression model, the main effect of genotype (coded as s group = 0 and l group = 1) was not significant, $b = -0.15$, SE = 0.21, $z = 0.72$, $P = 0.47$; the main effect of number of life events was significant, $b = 0.34$, SE = 0.06, $z = 5.70$, $P < 0.001$; and the interaction between genotype and number of life events was significant, $b = -0.30$, SE = 0.15, $z = 1.97$, $P = 0.05$.

mature. Nonetheless, although carriers of an s 5-HTTLPR allele who experienced four or more life events constituted only 10% of the birth cohort, they accounted for almost one-quarter (23%) of the 133 cases of diagnosed depression. Moreover, among cohort members suffering four or more stressful life events, 33% of individuals with an s allele became depressed, whereas only 17% of the l/l homozygotes developed depression (Fig. 3). Thus, the G × E's attributable risk and predictive sensitivity indicate that more knowledge about the functional properties of the 5-HTT gene may lead to better pharmacological treatments for those already depressed. Although the short 5-HTTLPR variant is too prevalent for discriminatory screening (over half of the Caucasian population has an s allele), a microarray of genes might eventually identify those needing prophylaxis against life's stressful events (*27*).

Evidence of a direct relation between the 5-HTTLPR and depression has been inconsistent (*12*), perhaps because prior studies have not considered participants' stress histories. In this study, no direct association between the 5-HTT gene and depression was observed. Previous experimental paradigms, including 5-HTT knockout mice (*13*), stress-reared rhesus macaques (*14*), and human functional neuroimaging (*15*), have shown that the 5-HTT gene can interact with environmental conditions, although these experiments did not address depression. Our study demonstrates that this G × E interaction extends to the natural development of depression in a representative sample of humans. However, we could not test hypotheses about brain endophenotypes (*28*) intermediate between the 5-HTT gene and depression because of the difficulty of taking CSF or functional magnetic resonance imaging measurements in an epidemiological cohort.

Much genetic research has been guided by the assumption that genes cause diseases, but the expectation that direct paths will be found from gene to disease has not proven fruitful for complex psychiatric disorders (*29*). Our findings of G × E interaction for the 5-HTT gene and another candidate gene, MAOA (*25*), point to a different, evolutionary model. This model assumes that genetic variants maintained at high prevalence in the population probably act to promote organisms' resistance to environmental pathogens (*30*). We extend the concept of environmental pathogens to include traumatic, stressful life experiences and propose that the effects of genes may be uncovered when such pathogens are measured (in naturalistic studies) or manipulated (in experimental studies). To date, few linkage studies detect genes, many candidate gene studies fail consistent replication, and genes that replicate account for little variation in the phenotype (*29*). If replicated, our G × E findings will have implications for improving research in psychiatric genetics. Incomplete gene penetrance, a major source of error in linkage pedigrees, can be explained if a gene's effects are expressed only among family members exposed to environmental risk. If risk exposure differs between samples, candidate genes may fail replication. If risk exposure differs among participants within a sample, genes may account for little variation in the phenotype. We speculate that some multifactorial disorders, instead of resulting from variations in many genes of small effect, may result from variations in fewer genes whose effects are conditional on exposure to environmental risks.

Infralimbic BDNF signaling is necessary for the beneficial effects of extinction on set shifting in stressed rats

Denisse Paredes[1], Anna R. Knippenberg[1] and David A. Morilak[1,2]✉

© The Author(s) 2021

Current pharmacotherapies for posttraumatic stress disorder (PTSD) and major depressive disorder (MDD) are ineffective for many patients, and often do not restore cognitive dysfunction associated with these disorders. Behavioral therapies, such as exposure therapy, can be effective for treatment-resistant patients. The mechanisms underlying exposure therapy are not well-understood. Fear extinction as an intervention after chronic stress can model the beneficial effects of exposure therapy in rats. Extinction requires neuronal activity and protein synthesis in the infralimbic (IL) cortex for its beneficial effects. We hypothesized that extinction requires Brain-Derived Neurotrophic Factor (BDNF) activity in the IL cortex to reverse stress-induced cognitive flexibility impairments. Extinction learning reversed set-shifting deficits induced by Chronic Unpredictable Stress (CUS), tested 24 h after extinction. Blocking BDNF signaling in the IL cortex during extinction by local administration of a neutralizing antibody prevented the beneficial effects of extinction on set shifting after stress. Extinction induced activation of the BDNF TrkB receptor, and signaling pathways associated with BDNF (Akt and Erk). Administration of exogenous BDNF into IL cortex in the absence of extinction was sufficient to reverse the effects of stress on set shifting. The effects of extinction were prevented by blocking either Erk or Akt signaling in the IL cortex, whereas the effects of exogenous BDNF were dependent on Erk, but not Akt, signaling. Our observations suggest that BDNF-Erk signaling induced by extinction underlies plastic changes that can reverse or counteract the effects of chronic stress in the IL cortex.

Neuropsychopharmacology; https://doi.org/10.1038/s41386-021-01171-7

INTRODUCTION

Psychiatric disorders such as posttraumatic stress disorder (PTSD) and major depressive disorder (MDD), are often comorbid, and affect millions of people every year [1, 2]. These disorders share pathological features, such as maladaptive shifts in coping behavior, and deficits in executive function. Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed pharmacotherapy for such disorders, but only approximately 60% of patients respond to treatment. Behavioral therapies, such as exposure therapy, can be effective [3]. However, only a small percentage of patients achieve full remission after exposure therapy [4]. Deciphering the neurobiological mechanisms underlying exposure therapy could lead to the development of strategies to improve therapeutic outcomes.

Cognitive flexibility is the ability to modify previously established associations, thoughts, or responses based on changes in the environment [30]. Cognitive flexibility deficits represent a symptom dimension shared across several psychiatric disorders, are associated with increased symptom severity in PTSD [5], and are a risk factor for developing MDD [6]. Set shifting is a form of cognitive flexibility that relies on the function of the medial prefrontal cortex (mPFC) [7], a brain region susceptible to the detrimental effects of stress [8]. Set shifting is a change in response strategy (i.e., a "cognitive set") that requires one to redirect attention from one perceptual dimension to another dimension previously irrelevant to the strategy [7]. Behavioral therapies, such as exposure therapy, address underlying cognitive dysfunction instead of targeting individual symptoms that may result from such dysfunction [9]. Exposure therapy has been shown to improve set shifting [10]. Behavioral therapies engage areas of the brain, such as the hippocampus, prefrontal cortex, and amygdala, that are affected by chronic stress [11].

Exposure therapy involves modifying one's cognitive appraisal of fear by utilizing fear extinction (FE) learning, a form of safety learning that consists of forming a new association between a conditioned stimulus and conditioned response [12, 13]. FE in rodents mimics some of the beneficial effects of exposure therapy [14, 15]. During FE, rodents learn that a previously conditioned stimulus (e.g., a tone) no longer signals an aversive stimulus (e.g., footshock). The resulting safety memory is formed through activity in the infralimbic (IL) portion of mPFC [16]. We have shown that extinction is effective in reversing stress-induced deficits in set shifting [14]. Extinction restores responsivity of the mPFC that is compromised by chronic stress and promotes adaptive active coping behavior, similar to the effects of exposure therapy in humans [17, 18]. These effects of extinction require activity-dependent protein translation in the IL [17]. However, the molecular mechanisms that modulate IL plasticity during extinction are not known.

Brain-Derived Neurotrophic Factor (BDNF) is necessary for extinction learning and consolidation in rodents and humans alike [19, 20]. Additionally, exogenous administration of BDNF into

the IL in the absence of extinction reduces fear (i.e., freezing) to the conditioned stimulus, mimicking extinction [21]. Therefore, we hypothesized that BDNF signaling in the IL may also be involved in the beneficial effects of extinction on set shifting after stress. BDNF can initiate plasticity through phosphorylation of its receptor, Tropomyosin receptor kinase B (TrkB), at tyrosine residues Y515 and Y816. Phosphorylation of Y515 activates the mitogen-activated protein kinase (MAPK)/extracellular regulated protein kinase (Erk) and phosphatidylinositol 3-kinase (PI3k)/protein kinase B (Akt) signaling pathways, both of which modulate neuronal plasticity and protein translation, and have been associated with extinction memory consolidation [22, 23], whereas TrkB phosphorylation at Y816 activates phospholipase C (PLC) signaling [24]. Dysregulation of both Erk and Akt signaling has been implicated in psychiatric disorders [25]. Erk and Akt are reduced in the mPFC and hippocampus of depressed and suicidal individuals, and studies report increases in Erk after antidepressant treatment [25]. Additionally, glucocorticoid exposure decreases phosphorylation of Erk in the hippocampus and increases immobility on the forced swim test [26]. We hypothesized that BDNF activity in the IL during extinction may be necessary to induce functional changes in stressed animals as a result of learning-induced activation of MAPK/Erk and/or PI3k/Akt signaling. Portions of this work have been presented in abstract form [27].

MATERIALS & METHODS

Animals

A total of 258 male and naturally cycling female rats (Envigo, 225–249 g) were group-housed on a 12/12 hr light cycle (lights on at 07:00 hr), with same-sex cagemates upon arrival. After 1 week of acclimation, they were single-housed and provided with food and water *ad libitum*. Experiments took place between 08:00-17:00 hr, during the lights-on portion of the cycle. All procedures were in accordance with NIH guidelines and approved by the UTHSA Institutional Animal Care and Use Committee.

Fear conditioning and extinction

Two days prior to the start of Chronic Unpredictable Stress (CUS) procedures, rats were habituated to two contexts in sound-attenuating cabinets for 15 min each. Context A consisted of a metal conditioning chamber (30.5 × 25.4 × 30.5 cm; model H10-11RC-TC-Sf) with square walls and a grid floor attached to a shock box (model H13–15). Context B was not associated with a shock and was in a different chamber, with pink and white vinyl floor and white vinyl circular walls.

Day 0 - Fear conditioning

Rats received fear conditioning or tone control treatment in Context A the day before the start of CUS. Fear conditioning consisted of four pairings of a tone (10 kHz, 75 dB, 20 s) coterminus with a footshock (0.8 mA, 0.5 s), with an inter-trial interval of 120 s. Freezing during each tone was quantified videographically by FreezeView software (ActiMetrics #ACT-100, Coulbourn Instruments). Tone-control rats were exposed to the tones but did not receive a shock.

Day 17 - Fear extinction

Three days after the end of CUS, all rats received a single fear extinction session in Context B. All rats were exposed to 16 tone-alone trials with no shock, with an average inter-trial interval of 120 s.

Chronic Unpredictable stress (CUS)

Chronic unpredictable stress was administered as previously described [17, 28]. For males, CUS consisted of 14 days of varied acute stressors: 30-min restraint, 1 h shake, 45 min social defeat, 10 min tail pinch, 24 h wet bedding, and 15 min mild footshock. We have reported that 14 days of CUS is not sufficient to induce set shifting deficits in females, so 21-day CUS was used for females, which induces the same set-shifting deficit as 14-day CUS in males [28]. CUS for females entailed mild footshock, tail pinch, shake stress, restraint, 24 hr wet bedding, and overnight lights on in place of social defeat.

Attentional set shifting test (AST)

The AST was used to measure cognitive flexibility on the extra-dimensional set shifting task as previously described [29]. A week prior to testing, animals were food restricted to 12 g/day for males and 9 g/day for females (~66% of average daily intake). Animals were trained and tested in a white plastic arena containing a start gate at one end and two terracotta pots separated by a Plexiglas wall at the other end. The AST consists of three days (habituation, training, and testing), with an extra day inserted between training and testing to allow for the administration of extinction:

i.Habituation day: Rats were trained to dig in pots filled with sawdust to retrieve a food reward, half a Honey Nut Cheerio (General Mills Cereals, Minneapolis, MN, USA).

ii. Training day: Rats were trained to locate the reward in one of two pots by discriminating cues in two stimulus dimensions: the odor applied to the rim of the pot or the texture of the digging medium that filled the pot.

iii. Treatment day: Rats received bilateral microinjections and extinction or tone control treatment.

iv. Testing day: The day after extinction, rats were tested on a series of discrimination tasks, in which a criterion of six correct consecutive trials was required to proceed to the next task (Table 1). Rats were tested using either medium or odor as the relevant dimension in the early discrimination tasks (i.e., simple discrimination, complex discrimination, reversal learning, intradimensional shift, second reversal), leading to the formation of a cognitive set. In the extra-dimensional (ED) set shifting task, the previously relevant dimension (e.g., odor), was irrelevant while the previously irrelevant dimension (medium) now indicated the location of the reward.

Western blotting

17 days after rats were fear conditioned or received tone control treatment, rats underwent fear extinction and 30 min later were sacrificed via rapid decapitation. In experiments where animals were stressed, rats were fear conditioned on day 0, then received stress or handling from days 1–14 for males or 1–21 days for females. On days 15-16 (days 22-23 for females), rats were left undisturbed to coincide with the experimental timeline of the AST experiments. On day 17 (24 for females), rats received fear extinction and were sacrificed 30 min after the end of extinction. The IL was dissected on ice from a 2 mm coronal slab cut 2–4 mm caudal to the frontal pole. Cortex adjacent and medial to the internal capsule was dissected from this slab, frozen in isopentane on dry ice, and stored at −80 °C until use. In preliminary experiments measuring phosphorylation of Y515 in IL at 0′, 30′, and 60′ post extinction, we found an increase in phosphorylation of Y515 at 30 min post extinction. Thus, we selected 30′ as our tissue collection time. Western blots were performed as described previously [30]. Membranes were incubated in anti-rabbit or mouse secondary antibody (1:5,000 Cell Signaling) detected using ECL Prime (GE Healthcare, Little Chalfont, UK). Membranes were stripped and re-probed with antibodies against total TrkB (1:1000, Neuromics, [31]), ERK (rabbit pAb 1:5000, Santa Cruz Biotechnology, sc-94), or Akt (mouse mAb 1:1,000, CST 29202). Images were captured using the G:BOX-XT4 Chemi system (Syngene; Frederick,MD). All experimental group samples were normalized to the mean of tone control samples run in the same assay.

Table 1. Stages of the Attentional Set Shifting Test (AST). Order of discrimination stages used for AST. All data shown are from the extra dimensional (ED) set shifting task.

	Dimensions		Example combinations	
Discrimination stage	Relevant	Irrelevant	(+)	(−)
Simple	Odor		Clove/sawdust	Nutmeg/sawdust
Compound	Odor	Medium	Clove/raffia	Nutmeg/yarn
			Clove/yarn	Nutmeg/raffia
Reversal 1	Odor	Medium	Nutmeg/raffia	Clove/yarn
			Nutmeg/yarn	Clove/raffia
Intradimensional shift	Odor	Medium	Rosemary/wood balls	Cinnamon/plastic beads
			Rosemary/plastic beads	Cinnamon/wood balls
Reversal 2	Odor	Medium	Cinnamon/plastic beads	Rosemary/wood balls
			Cinnamon/ wood balls	Rosemary/plastic beads
Extradimensional shift (ED)	Medium	Odor	Velvet/citronella	Crepe/thyme
			Velvet/thyme	Crepe/citronella

Extinction with microinjections of BDNF neutralizing antibody and signaling pathway inhibitors

Rats were implanted with microinjection guide cannulae (Plastics One, Roanoke, VA) positioned 1 mm above the IL (AP + 2.9, ML −3.1, DV −3.8) at a 30° angle to minimize disruption of the prelimbic cortex. After the completion of experiments, a subset of rat brains from each group was used to verify cannula placement. Animals recovered for 1 week after surgery. On day 0, they received fear conditioning or tone exposure and on days 1–14 (1–21 for females), they underwent CUS. In this experiment and the next, in which exogenous BDNF was administered (below), males received overnight lights on in place of social defeat to make their CUS protocol identical to that of females except for the duration. There was no difference in the effect of CUS. On days 15–16, they were habituated and trained on the AST. On day 17, they received bilateral microinjection prior to extinction training. Infusion cannulae were inserted, extending 1 mm beyond the guide cannulae. Rats received bilateral injections of sheep IgG or sheep anti-BDNF (EMD Millipore, Billerica, MA), 0.5 µg/0.5 µl per side at a rate of 0.1 µl/min prior to extinction. This dose was shown to block BDNF signaling [24]. The injector remained in place for 2 min for diffusion. Twenty minutes after completing microinjections, rats underwent extinction. 24 h following extinction and microinjections, rats were tested on the set shifting test. For experiments involving kinase inhibitors, rats received bilateral microinjections of the PI3k inhibitor LY294002 (4.3 ng/0.5 µl/side), the Erk inhibitor PD98059 (2 µg/0.5 µl/side), or vehicle. As the different vehicles (0.5% DMSO in saline, 70% DMSO in saline, or saline alone) did not differ and had no effect on behavior, these groups were combined into a single vehicle group to minimize animal usage. Both LY294002 and PD98059 at the selected doses effectively inhibit phosphorylation of Akt and Erk in vivo, respectively [30, 32]. Based on preliminary western blot experiments showing phosphorylation of TrkB at Y515 occurred 30 mins post FE, we administered the inhibitors immediately after the end of the 32-minute extinction session so drug administration would precede induction of phosphorylation of Y515. One day later, rats were tested on the AST.

Microinjections of BDNF peptide and signaling pathway inhibitors in place of extinction

Rats were implanted with microinjection guide cannulae (Plastics One, Roanoke, VA) positioned 1 mm above the IL (AP + 2.9, ML −3.1, DV −3.8) at a 30° angle. Animals recovered for one week after surgery. On days 1–14 for males and days 1–21 for females, rats underwent CUS. On days 15-16 (22–23 for females) they were habituated and trained on the AST. On day 17 (24 for females), they received bilateral microinjections (0.75 µl/side) into IL of BDNF alone (0.5 µg/µl, R&D Systems), or a combination of BDNF after either the PI3k inhibitor LY294002 (4.3 ng/0.5 µl/side), the Erk inhibitor PD98059 (2 µg/0.5 µl/side), or vehicle (0.5% DMSO in 0.9% saline or saline). The inhibitors were injected first, followed by BDNF. The microinjector remained in place for 2 min to allow diffusion. 24 h after microinjections, rats were tested on the set shifting test.

RESULTS

The BDNF receptor TrkB is phosphorylated in IL at Y515 but not Y816 after fear extinction

32 rats were used in 2 groups (tone controls vs. extinction), subsets of which were used to assess phosphorylation of TrkB at Y515 (9–10 males, 5–8 females), and Y816 (7–8 males, 4–5 females) in the IL cortex. In the aggregate analysis, extinction increased phosphorylation of TrkB at Y515 compared to tone controls in the IL 30 min after extinction ($t_{30} = 3.432$, $p = 0.0018$, Fig. 1A). Broken out by sex, a student's *t*-test showed an effect of extinction on Y515 in males ($t_{17} = 3.568$, $p = 0.0024$). In females, the effect of extinction on Y515 phosphorylation was not significant, although these experiments were not specifically powered for separate analyses by sex ($t_{11} = 1.222$, $p = 0.2474$). Extinction did not induce an increase at Y816 ($t_{22} = 0.4897$, $p = 0.6292$; Fig. 1B). There was no effect of extinction on Y816 in either males (7-8/group; $t_{13} = 0.00213$, $p = 0.9983$, Fig. 1B, top inset) or females (4–5/group; $t_7 = 0.6168$, $p = 0.5569$; Fig. 1B, bottom inset). Therefore, 30 min after extinction, BDNF-TrkB signaling is initiated in the IL by phosphorylation of Y515 but not Y816. Fig. 1C shows the typical pattern of freezing behavior during presentation of the tone during fear conditioning and extinction.

The BDNF receptor TrkB is phosphorylated at Y515 in the IL of both stressed and control animals after the extinction

To test whether extinction also increases phosphorylation at Y515 in stressed rats, 35 rats (18 males, 4–9/group; 17 females, 4–5/group) were used in 4 groups (stress or unstressed x extinction or tone controls) for western blotting. There was no difference in extinction between stress and control groups ($F_{1,16} = 0.03366$, $p = 0.8567$, Fig. 2A). ANOVA revealed a main effect of extinction, indicating an increase in phosphorylation of Y515 in IL ($F_{1,31} = 5.073$, $p = 0.0315$). There was no interaction ($F_{1,31} = 0.9371$, $p = 0.3405$), and no main effect of stress ($F_{1,31} = 1.794$, $p = 0.1901$; Fig. 2B). When data were analyzed separately by sex (Fig. 2B insets), the results were similar but did not reach significance (for males: stress, $F_{1,14} = 0.2007$, $p = 0.6610$; extinction,

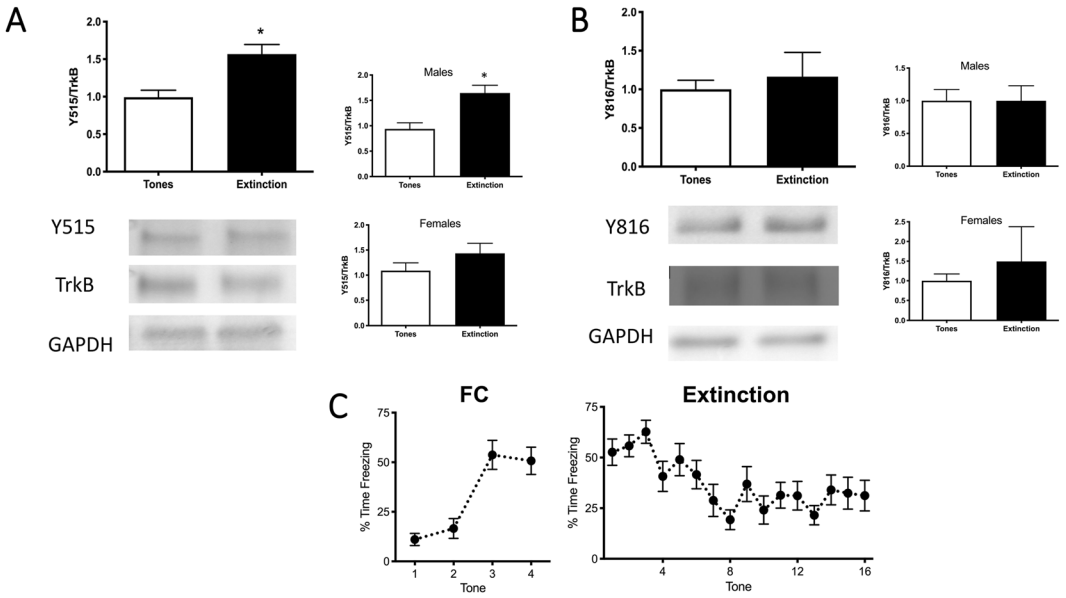

Fig. 1 Extinction induces the phosphorylation of the BDNF receptor TrkB at Y515, but not Y816 in the IL. A Phosphorylation of TrkB at Y515 is increased in the IL 30 min after the end of extinction compared to tone controls (*$p = 0.0018$, $n = 14$–18/group). Insets show data for males and females separately; a student's *t*-test showed an effect of extinction on Y515 in males ($t_{17} = 3.568$, $p = 0.0024$) but not in females alone. **B** Phosphorylation of TrkB at Y816 was unchanged 30 min after the end of extinction compared to tone controls ($p = 0.6292$, $n = 12$/group), insets show males and females separately. Bars represent SEM. **C** Fear conditioning (left) and extinction (right) curves showing % time freezing during the presentation of the tone. Bars represent SEM.

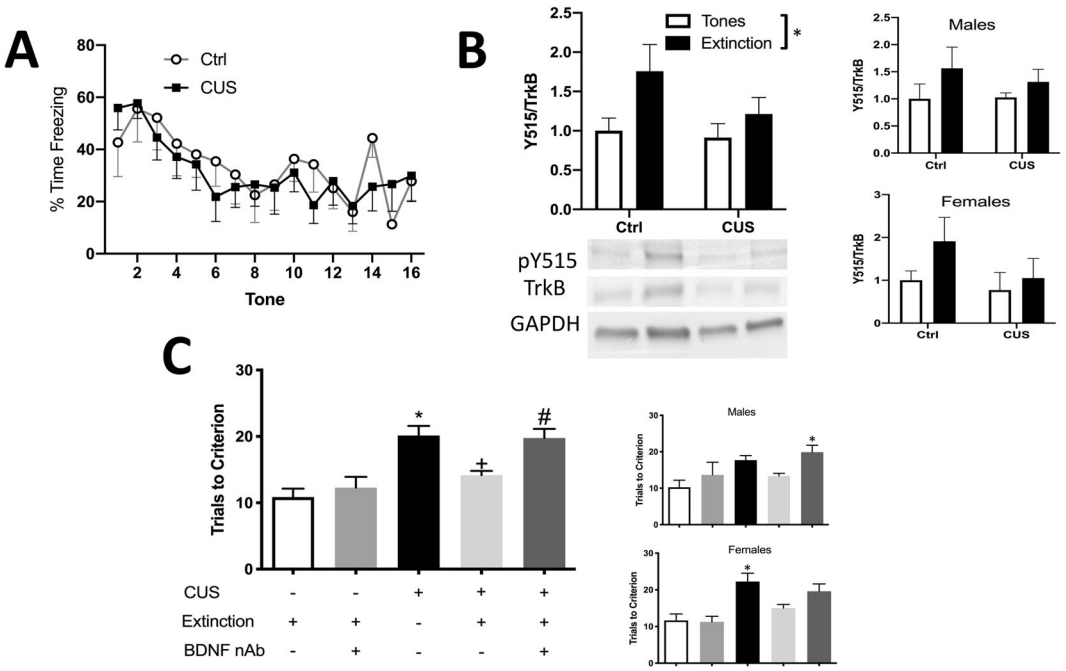

Fig. 2 Infralimbic BDNF is necessary for the effects of extinction on set shifting in stressed animals. A Fear extinction curves in stressed and non-stressed rats, showing percent time freezing during tone presentation. Bars represent SEM. **B** Extinction induced an increase in phosphorylation of TrkB at Y515 compared to tone controls (*$p = 0.0315$; 8–9 rats/group). Insets show males and females separately. **C** CUS impaired set shifting on the AST (CUS/Tones/IgG compared to No Stress/Extinction/IgG, *$p = 0.0003$), and extinction rescued set shifting in stressed rats (CUS/Extinction/IgG compared to CUS/Tones/IgG, +$p = 0.0091$). Blocking BDNF in the IL at the time of extinction attenuated the beneficial effect of extinction in stressed rats (CUS/Extinction/anti-BDNF compared to CUS/Extinction/IgG, #$p = 0.0218$). The BDNF antibody alone had no effect in non-stressed control rats (No stress/Extinction/anti-BDNF compared to No stress/Extinction/IgG, $p = 0.9739$). Insets show males and females separately. In males, multiple comparisons showed a difference between No stress/extinction/control IgG vs CUS/extinction/anti-BDNF. In females, multiple comparisons showed differences between No stress/extinction/control IgG vs CUS/tones/IgG. Bars represent SEM.

$F_{1,14} = 2.844$, $p = 0.1138$; interaction, $F_{1,14} = 0.3002$, $p = 0.5924$; for females: stress, $F_{1,13} = 1.794$, $p = 0.2034$; extinction ($F_{1,13} = 1.499$, $p = 0.2425$; interaction, $F_{1,13} = 0.5060$, $p = 0.4894$). There was no correlation between extinction, expressed as the freezing index

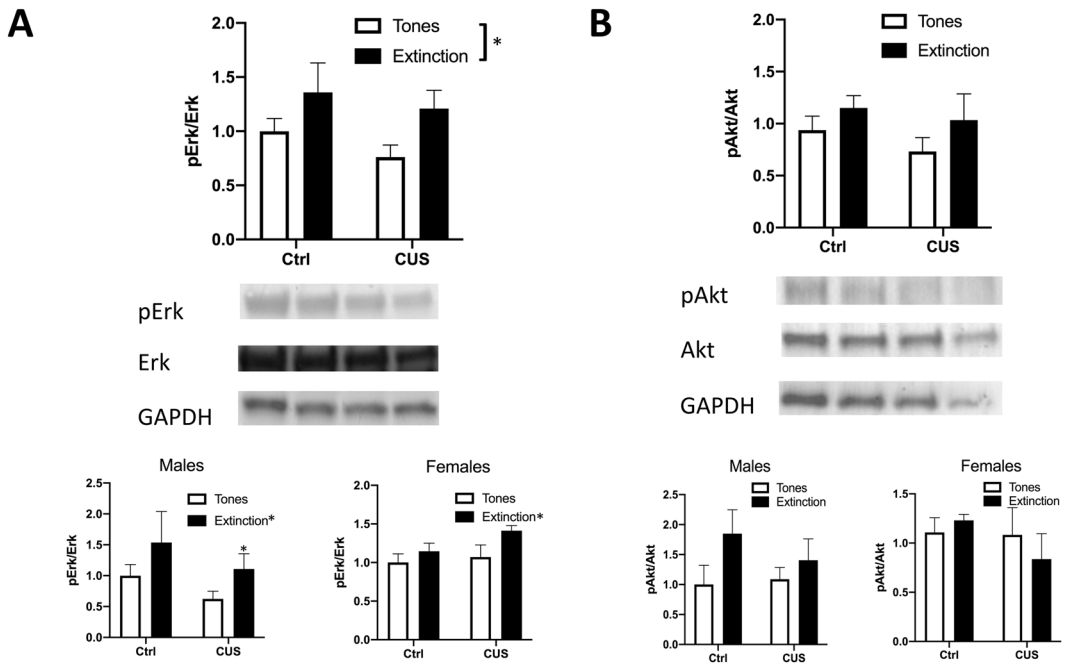

Fig. 3 Extinction induces the phosphorylation of Erk but not Akt in the IL. A Extinction increased phosphorylation of Erk in the IL 30 min after extinction compared to tone controls (*$p = 0.0021$, $n = 12$–14/group). Insets show males and females separately. ANOVA on male data showed a main effect of extinction on pErk ($F_{1,30} = 8.469$, $p = 0.0067$), a main effect of stress ($F_{1,30} = 5.136$, $p = 0.038$), and a difference between Tones CUS vs Extinction Control ($p = 0.0074$). Extinction induced an increase in pErk in females and a difference between Tones-CUS vs Extinction-CUS $p = 0.0023$). **B** Extinction did not significantly increase the phosphorylation of Akt in the IL 30 min after the end of extinction compared to tone controls ($p = 0.1639$, $n = 11$–14/group). Insets show males and females separately.

(mean freezing at plateau on tones 9–16 / mean initial freezing on tones 2–4) and pTrkB Y515 levels ($r_{18} = -0.2789$, $p = 0.2623$).

BDNF activity in IL cortex during extinction is necessary for its effects on set shifting

In total, 54 rats (28 males, 3–7/group; 26 females, 3–8/group) were used in five groups: (1) control group with control IgG in the IL (No stress/extinction/control IgG), (2) control group with neutralizing antibody against BDNF in the IL (No stress/extinction/anti-BDNF), (3) stress + tone control (CUS/tones/IgG), (4) extinction treatment (CUS/extinction/IgG), and 5) a group to test the necessity of BDNF for the effects of extinction (CUS/extinction/anti-BDNF). ANOVA revealed a significant group effect on set shifting ($F_{4,49} = 9.544$, $p < 0.0001$; Fig. 2C). Pairwise comparisons using the Holm–Sidak test showed that CUS impaired set shifting (CUS/Tones/IgG compared to No Stress/Extinction/IgG, $p = 0.0003$). Extinction rescued set shifting in stressed rats (CUS/Extinction/IgG compared to CUS/Tones/IgG, $p = 0.0091$), and blocking BDNF in the IL attenuated the beneficial effect of extinction (CUS/Extinction/anti-BDNF compared to CUS/Extinction/IgG, $p = 0.0218$). There was no effect of BDNF antibody alone on set shifting in non-stressed rats (No stress/Extinction/anti-BDNF compared to No stress/Extinction/IgG, $p = 0.9739$). These results suggest that BDNF activity in IL cortex is necessary during extinction for its beneficial effect on set shifting in stressed animals. As reported previously [17, 29] there was no effect of the treatments on fear extinction, as the extinction curves did not differ between groups ($F_{5,47} = 0.8359$, $p = 0.5310$). Analysis of male data alone revealed a significant group effect on set shifting ($F_{4,23} = 4.662$, $p = 0.0067$). Holm–Sidak multiple comparisons showed a difference between No stress/extinction/control IgG vs CUS/extinction/anti-BDNF ($p = 0.0110$); other group comparisons were not significant. ANOVA also revealed a significant group effect in females ($F_{4,21} = 5.726$, $p = 0.0028$); Holm–Sidak multiple comparisons showed differences between No stress/extinction/control IgG vs CUS/tones/IgG ($p = 0.0263$).

Extinction induces the phosphorylation of Erk but not Akt in the IL of stressed and control animals

In total, 51 rats (34 males, 8–10/group, 23 females, 4–7/group) were used in four groups (stress x extinction) to assess phosphorylation of Erk in the IL after extinction. ANOVA revealed a main effect of extinction ($F_{1,47} = 10.60$, $p = 0.0021$; Fig. 3A), no interaction ($F_{1,47} = 0.4968$, $p = 0.4844$), and no main effect of stress ($F_{1,47} = 2.375$, $p = 0.1300$). ANOVA on male data showed a main effect of extinction on pErk ($F_{1,30} = 8.469$, $p = 0.0067$), a main effect of stress ($F_{1,30} = 5.136$, $p = 0.038$), and no significant interaction ($F_{1,30} = 0.1545$, $p = 0.6971$). Holm–Sidak multiple comparisons showed a difference between Tones CUS vs Extinction Control ($p = 0.0074$). Extinction induced an increase in pErk in females ($F_{1,19} = 10.07$, $p = 0.005$) and a significant interaction ($F_{1,19} = 4.75$, $p = 0.0421$), but no main effect of stress ($F_{1,19} = 0.5888$, $p = 0.4523$). Holm–Sidak multiple comparisons showed a difference between Tones-CUS vs Extinction-CUS in females ($p = 0.0023$).

54 rats (25 males, 5–8/group; 18 females, 5–7/group) were used to assess pAkt. ANOVA revealed no significant main effect of stress ($F_{1,45} = 2.038$, $p = 0.1603$), no effect of extinction ($F_{1,45} = 0.8007$, $p = 0.3756$), and no interaction ($F_{1,45} = 0.05960$, $p = 0.8082$; Fig. 3B). Also, no significant effects were seen when data were analyzed separately by sex.

The PI3k-Akt and MAPK-Erk signaling pathways are involved in the therapeutic effects of extinction on set shifting after stress

In total, 62 rats (35 males, 3–7/group; 27 female rats, 3–5/group) were used in seven groups: (1) a control group (no stress/vehicle/extinction), (2) a control group with PI3k inhibitor LY294002 alone (no stress/LY294002/extinction), (3) a control group with MAPK inhibitor PD98059 alone (no stress/PD98059/extinction), (4) stress + tone control group (CUS/vehicle/tones), (5) extinction treatment (CUS/vehicle/extinction), (6) a group to determine the effect of blocking PI3k on the effects of extinction

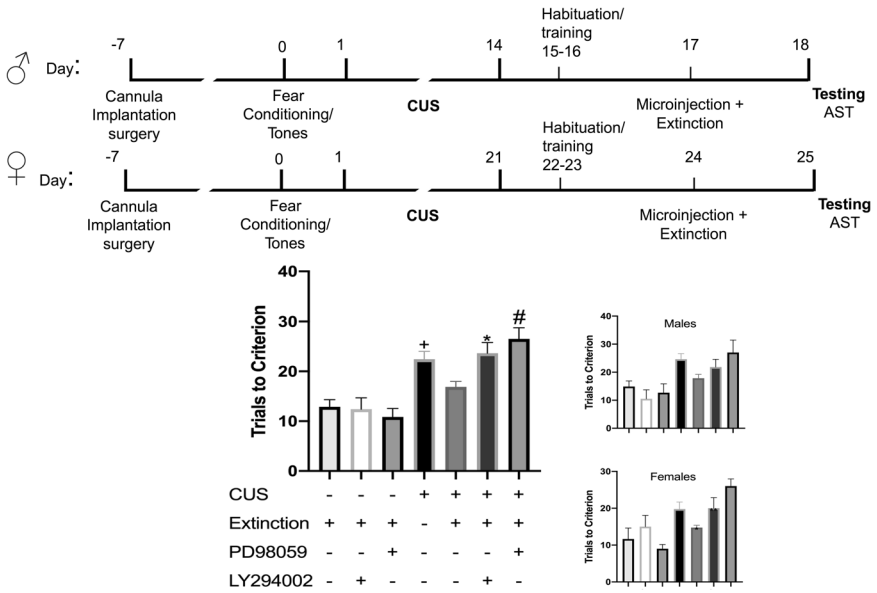

Fig. 4 Erk and Akt signaling are required in the IL cortex for the beneficial effects of extinction on set shifting in stressed animals. Microinjections of either LY200492 or PD98059 into the IL cortex immediately after extinction blocked the effects of extinction on set-shifting 24 h later in stressed rats. CUS induced a deficit in set shifting (CUS Tones Veh vs Ctrl Ext Veh, $+p = 0.0026$). Both PD98059 and LY294002 attenuated the improvement in set-shifting induced by extinction in stressed animals (CUS Ext Veh vs CUS Ext PD98059: $\#p = 0.0031$; CUS Ext Veh vs CUS Ext LY294002: $*p = 0.0389$). Insets show males and females separately.

(CUS/LY294002/extinction), and (7) a group to determine the effects of blocking MAPK on the effects of extinction (CUS/PD98059/extinction). ANOVA revealed a significant group effect ($p < 0.0001$, $F_{6,55} = 11.44$; Fig. 4). Holm–Sidak post hoc tests showed an effect of stress (CUS Tones Veh vs Ctrl Ext Veh, $p = 0.0026$). Neither inhibitor alone affected set shifting in control animals (Ctrl Ext Veh vs Ctrl Ext LY294002: $p = 0.95$, Ctrl Ext Veh vs Ctrl Ext PD98059: $p = 0.93$). Extinction again had a beneficial effect after stress, as the performance of extinction-treated stressed animals was comparable to control animals (Ctrl Ext Veh vs CUS Ext Veh, $p = 0.63$). Both PD98059 and LY294002 attenuated performance in stressed animals that received extinction (CUS Ext Veh vs CUS Ext PD98059: $p = 0.0031$; CUS Ext Veh vs CUS Ext LY294002: $p = 0.0389$). Therefore, blocking either MAPK/Erk or PI3k/Akt signaling immediately after extinction blocked the beneficial effects on set shifting tested 24 h after extinction in stressed animals. As above, there was no effect of the treatments on extinction itself, as the extinction curves did not differ between groups ($F_{3,34} = 0.5311$, $p = 0.6640$). One way ANOVA on male data only revealed a significant group effect ($F_{6,27} = 5.3879$, $p = 0.0009$, Fig. 4 inset). However, as this experiment was not specifically powered to analyze separately by sex, Holm–Sidak multiple comparisons revealed no significant differences between groups: CUS Ext Veh vs CUS Ext PD98059 ($p = 0.2896$), Ctrl Ext Veh vs CUS Tones Veh ($p = 0.0555$), CUS Ext Veh vs CUS Ext PD98059 ($p = 0.2896$), CUS Ext Veh vs CUS Ext LY294002 ($p = 0.7769$). One way ANOVA on female data also revealed a significant group effect ($F_{6,19} = 6.937981$, $p = 0.0005$), but Holm–Sidak multiple comparisons revealed no specific group differences: Ctrl Ext Veh vs CUS tones Veh ($p = 0.4167$), CUS Ext Veh vs CUS Tones Veh ($p = 0.7460$), CUS Ext Veh vs CUS Ext LY294002 ($p = 0.0546$) and CUS Ext Veh vs CUS Ext PD98059 ($p = 0.0662$).

BDNF alone reverses the effects of CUS on set shifting, and Erk signaling but not PI3k signaling is necessary for the effects of BDNF

In total, 24 rats (12 males, 3/group; 12 females, 3/group) were used in four groups: (1) a stress group (CUS/saline), (2) a group to determine whether BDNF alone microinjected into IL cortex in place of extinction is sufficient to reverse the effects of stress (CUS/BDNF), (3) a group to test whether the effects of BDNF are blocked by the PI3k inhibitor (CUS/BDNF/LY294002), and (4) a group to test whether the effects of BDNF are blocked by the MAPK inhibitor (CUS/BDNF/PD98059). ANOVA revealed a significant group effect ($F_{3,20} = 5.602$, $p = 0.0059$, Fig. 5). Multiple comparisons Holm–Sidak test showed that CUS-BDNF animals performed better than CUS-vehicle animals ($p = 0.0349$), while CUS-BDNF-PD90859 treated rats did not perform better than CUS-Veh animals ($p = 0.9616$). By contrast, stressed rats that received BDNF and the PI3k inhibitor still performed better than CUS-Veh animals ($p = 0.0408$), and were not significantly different than CUS-BDNF alone ($p = 0.9616$). Further, rats treated with BDNF and the Erk inhibitor PD90859 performed worse than CUS-BDNF ($p = 0.0385$). Therefore, BDNF alone in the IL cortex reversed the effects of stress on set shifting, and this effect was blocked by inhibiting Erk signaling, but not PI3k. One way ANOVA on male data alone revealed a significant group effect $F_{3,8} = 6.050$, $p = 0.0187$, Fig. 5). Holm–Sidak revealed no differences between CUS–Veh males compared to CUS-BDNF males ($p = 0.3273$), but did detect a difference between CUS-Veh and CUS/BDNF/LY294002 ($p = 0.0312$). No differences were observed in CUS-BDNF vs CUS/BDNF/PD98059 in males ($p = 0.3273$). A one way ANOVA revealed no group differences in female data analyzed separately ($F_{3,8} = 3.652$, $p = 0.0635$); thus, pairwise comparisons were not performed.

DISCUSSION

The results of this study demonstrate the necessity of BDNF activity in the IL for the beneficial effects of extinction on restoring stress-induced cognitive deficits in both male and female rats. Our findings are consistent with previous work highlighting the role of BDNF in extinction-mediated plasticity [21]. In humans, the BDNF Val66Met polymorphism, a single nucleotide polymorphism associated with reduced BDNF release, increases the risk of developing PTSD, and is associated with a poorer response to exposure therapy [33, 34]. Thus, compounds that enhance fear extinction by promoting BDNF activity may be clinically relevant to the treatment of PTSD and MDD [11]. Following exposure

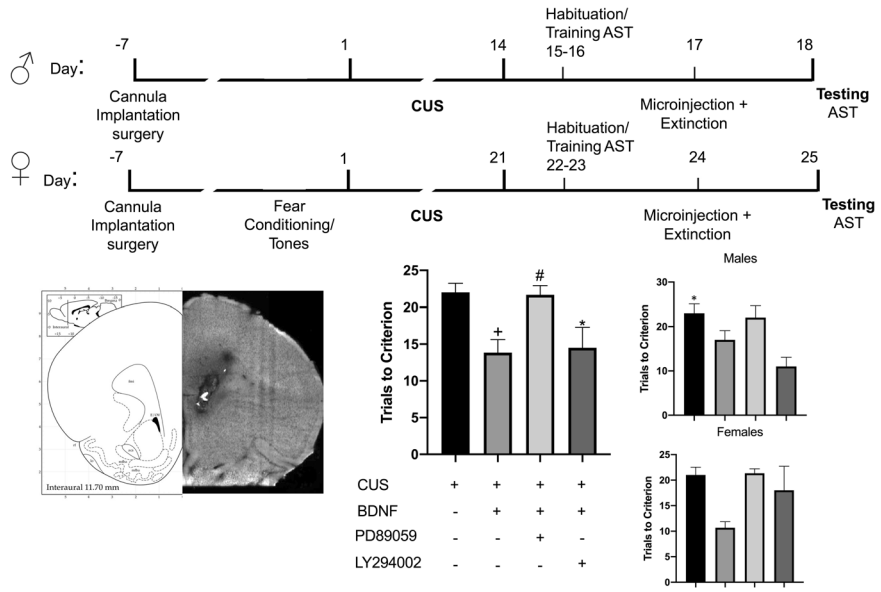

Fig. 5 Exogenous BDNF administered in the IL cortex reverses the effects of stress on set shifting, and these effects are dependent on Erk signaling. CUS-BDNF animals performed better than CUS-vehicle-treated animals ($+p = 0.0349$, $n = 6$ rats/group). Stressed rats that received BDNF and the PI3k inhibitor LY294002 performed better than CUS-Veh animals ($*p = 0.0408$), and were not significantly different than CUS-BDNF alone ($p = 0.9616$). By contrast, stressed rats treated with BDNF and the Erk inhibitor PD90859 performed worse than CUS-BDNF rats ($\#p = 0.0385$). Insets show males and females separately. In males, Holm–Sidak tests showed a difference between CUS-Veh and CUS/BDNF/LY294002 ($p = 0.0312$). Bars represent SEM. Bottom left is a representative example of injection site localization by dye injection into the IL.

therapy, symptoms may take weeks or months to improve, and a small number of patients achieve remission. Our results suggest that pharmacotherapies enhancing BDNF/Erk signaling in the mPFC may be advantageous as adjuncts to behavioral therapy. For example, studies have demonstrated the role of BDNF and Erk signaling in the antidepressant effects of ketamine [35], which is effective in treatment-resistant patients. Indeed, a recent pilot study showed that extinction and reconsolidation combined with adjunct administration of ketamine were effective in treating PTSD [36].

Several studies have demonstrated a role for BDNF in restoring mPFC function compromised by stress [37, 38]. Chronic stress induces functional and morphological alterations in the mPFC, such as dendritic atrophy of pyramidal neurons and reduced expression of glutamate receptors [39, 40], whereas BDNF induces long-term potentiation (LTP), enhances neuronal excitability, glutamate receptor trafficking, and promotes local protein synthesis in dendrites [41]. Extinction restores mPFC responsivity compromised by stress [17], and requires de novo protein synthesis in the IL for its beneficial effects. The current results suggest that BDNF activity in the IL during extinction facilitates the restoration of mPFC responsivity after stress, perhaps by promoting the synthesis of plasticity-related proteins. This hypothesis requires further testing. We observed phosphorylation of the BDNF receptor TrkB in IL after extinction, consistent with reports suggesting the activity-dependent release of BDNF during extinction [21]. After extinction learning, BDNF is increased in ventral hippocampal neurons [42]. Release of BDNF from ventral hippocampal projections to the IL is crucial for extinction memory [42]. Local release of BDNF elicits dendritic growth [43], a mechanism through which extinction-induced BDNF release in IL may reverse the detrimental effects of stress.

Inducing plasticity in the IL via extinction may also reverse stress-induced behavioral impairments mediated in other brain regions innervated by IL cortex. During extinction, the IL exerts inhibitory control over the amygdala to suppress fear. In individuals with PTSD, mPFC hypoactivity and amygdala hyperresponsivity are predictive of poor response to cognitive behavioral therapy [44]. Restoring IL function via BDNF signaling may therefore correct amygdala hyperresponsiveness and exaggerated fear response by enhancing activity in the mPFC. The IL also projects to the lateral septum (LS), which mediates active coping behavior in the shock probe defensive burying test (SPDB) [45, 46]. We have reported that extinction corrects the maladaptive shift from active to passive coping in the SPDB after chronic stress, and this effect relies on IL activity [17]. Thus, BDNF-induced plasticity in IL cortex during extinction may improve active coping behavior by facilitating modulatory regulation of LS activity by IL after stress.

The current results also elucidate intracellular signaling mechanisms potentially involved in the effects of extinction. Both Akt and Erk signaling contributed to the beneficial effects of extinction on set shifting that had been compromised by stress. Both Akt and Erk signaling contribute to long-term memory formation [47, 48]. Therefore, inhibiting these pathways likely interferes with extinction memory consolidation in the IL, which may reduce the subsequent therapeutic effects of extinction after stress. Extinction induced a significant increase in Erk phosphorylation, but only a modest, non-significant increase in phosphorylated Akt, consistent with previous reports [22]. This may seem at odds with the demonstration that PI3k blockade attenuated the beneficial effects of extinction. However, it is possible that only a small fraction of the total pool of Akt is activated by extinction, or that an increase in Akt phosphorylation only occurs in some cells after extinction, making it difficult to detect against a large unaffected background. Our results suggest, however, that even if the increase in phosphorylation is modest after extinction, Akt signaling is nonetheless necessary for the beneficial effects of extinction on set shifting. Another possibility is that, in addition to BDNF activity, extinction may also invoke other processes and transmitters that require basal PI3k-Akt activity in the IL, independent of induction by BDNF, to promote plasticity beneficial to set shifting. For example, Insulin Growth Factor-2 signals via PI3k-Akt, and has been shown to be involved in the consolidation of fear extinction, making it another

potential candidate for inducing plasticity through actions of PI3k-Akt [49].

Administration of exogenous BDNF into the IL in lieu of extinction reversed the effects of stress on set shifting, and this required Erk, but not Akt signaling. Although Erk and Akt share common targets, these pathways have different roles in some BDNF-related processes [47–49]. These results are in agreement with studies demonstrating the importance of Erk signaling for memory- and BDNF-induced plasticity [50–52]. Erk activation is necessary for BDNF-induced dendritic spine formation [50], and extinction increases dendritic spine density after acute stress [53]. Moreover, BDNF requires Erk signaling to phosphorylate cyclic AMP response element-binding protein (CREB) which mediates memory phase transitions [54]. BDNF/Erk-induced CREB activation drives the expression of genes regulating LTP and neuronal plasticity, e.g., activity-regulated cytoskeleton-associated protein (Arc) and Zif268 [55]. Thus, it is likely that extinction, via BDNF-Erk signaling, induces structural and functional plasticity in the IL necessary for memory consolidation, and for the beneficial effects of extinction on stress-compromised cognitive function such as set shifting.

In sum, the current results replicated our previous reports that extinction reversed stress-induced deficits in set shifting [17, 29] in both males and females, and demonstrated that these beneficial effects of extinction are dependent on BDNF activity in the IL during extinction. Extinction phosphorylated TrkB at the Y515 residue, but not Y816, suggesting a potential role for Y515-initiated intracellular signaling for the effects of extinction. Inhibiting either Akt or Erk in the IL after extinction prevented the therapeutic effects of extinction in stressed animals, and extinction increased phosphorylation of Erk, but not Akt, in the IL cortex. We further showed that exogenous BDNF microinjected into the IL was sufficient to reverse the detrimental effects of stress on set shifting, mimicking the beneficial effects of extinction. The beneficial effects of BDNF alone were mediated by Erk, but not Akt signaling. This information may be useful in developing strategies for adjunctive treatment during exposure therapy for PTSD to enhance or accelerate therapeutic efficacy and improve treatment outcomes.

ABSTRACT

One hallmark of psychiatric conditions is the vast continuum of individual differences in susceptibility vs. resilience resulting from the interaction of genetic and environmental factors. The environmental enrichment paradigm is an animal model that is useful for studying a range of psychiatric conditions, including protective phenotypes in addiction and depression models. The major question is how environmental enrichment, a non-drug and non-surgical manipulation, can produce such robust individual differences in such a wide range of behaviors. This paper draws from a variety of published sources to outline a coherent hypothesis of inoculation stress as a factor producing the protective enrichment phenotypes. The basic tenet suggests that chronic mild stress from living in a complex environment and interacting non-aggressively with conspecifics can inoculate enriched rats against subsequent stressors and/or drugs of abuse. This paper reviews the enrichment phenotypes, mulls the fundamental nature of environmental enrichment vs. isolation, discusses the most appropriate control for environmental enrichment, and challenges the idea that cortisol/corticosterone equals stress. The intent of the inoculation stress hypothesis of environmental enrichment is to provide a scaffold with which to build testable hypotheses for the elucidation of the molecular mechanisms underlying these protective phenotypes and thus provide new therapeutic targets to treat psychiatric/neurological conditions.

1. A history of environmental enrichment research

The "nature vs. nurture" debate began in earnest during the Victorian period, championed by Sir Francis Galton, who was inspired by the works of his cousin Charles Darwin. At issue was whether a person's expressed traits are a product of heritability (i.e. nature) or by his/her own experiences (nurture). Galton, bolstered by Darwin's theories on heritability came down firmly on the side of "nature". The opposing "nurture" side of the debate was best defined centuries before by John Locke's borrowed term "tabula rasa" (i.e. blank slate). The "nurture" side of the argument was further strengthened in the early 1900s by John Watson's theories on behaviorism.

As science evolved (particularly the advent of genetics), the "nature vs. nurture" debate evolved into a "genes vs. environment" debate, respectively. The battle raged on as scientists on both sides of the argument produced irrefutable evidence for their view. Eventually, scientists realized that both arguments were correct— that a person's expressed phenotype was due to an interaction of genes with environment. Thus, the Gene/Environment Interaction Theory was born. In a basic sense, the environment controls (to some degree) how genes are expressed. Thus, gene transcription is where the proverbial "rubber hits the road" and seems to play a significant role in the protective phenotypes produced by environmental enrichment (Green et al., 2010; Lobo et al., 2013; Zhang et al., 2014), which are described below in the beneficial effects of environmental enrichment.

The beginning of modern environmental enrichment research is mostly attributed to Rosenzweig, Renner, Bennett, Diamond and colleagues. This group used the environmental enrichment paradigm to show convincingly that the adult brain still exhibits plasticity and that, just like muscles, brains get stronger with greater use. Rats reared in an enriched condition (EC) have a thicker cortex, more dendritic arborization and greater cognitive abilities than rats reared in an isolated condition (IC) (Diamond et al., 1964; Renner and Rosenzweig, 1987; Rosenzweig and Bennett, 1996). Following these early experiments, many others have used environmental enrichment and found it to be a useful animal model in a variety of fields, particularly because it is a non-drug and non-surgical manipulation.

In parallel with Rosenzweig and colleagues, Harry Harlow was finalizing the ideas for his seminal work on the importance of maternal and social enrichment in rhesus monkeys (Harlow, 1958). Harlow designed inanimate wire and cloth "surrogate" mothers to show that maternal contact is enriching to baby macaques beyond merely providing food. Although Harlow's early work was oriented to the positive effects of maternal enrichment (i.e. affection), his later work shifted perspective to focus on the isolation aspect (i.e. lack of enrichment) rather than the enrichment itself (Harlow and Suomi, 1971).

2. What is environmental enrichment?

Environmental enrichment is complex and there are numerous ways to provide enrichment. There is a lack of consistency in protocols for enrichment between different laboratories, but the most common procedure in rats involves rearing the subjects in a large cage with novel objects and social contact with conspecifics for at least 30 days beginning immediately after weaning. The objects are replaced and rearranged daily to maximize novelty. This arrangement provides three key facets of enrichment: novelty, social contact and exercise. It has been shown in rats that all three aspects are rewarding (Bardo and Bevins, 2000; Belke, 2000; Bevins and Bardo, 1999) and all three release dopamine in the nucleus accumbens (Greenwood et al., 2011; Louilot et al., 1986; Rebec et al., 1997). Thus, it can be said that environmental enrichment is a compound manipulation that provides a daily workout for the dopamine system. Indeed, when the novel objects are replaced each day, the rats display a burst of exploratory activity lasting approximately 30 min that is beyond anything seen with locomotor stimulants like cocaine or amphetamine. Additionally, there is a second burst of exploratory/play behavior that occurs at the onset of the dark cycle, the beginning of the rats' normal period of high activity.

Although environmental conditions have a dramatic impact on the behavior of animals, these differing protocols for enriching rats often produce conflicting results. Parameters such as age of the animal, degree of enrichment, duration of enrichment, species and sex can each affect the results of an experiment. The lack of consistency in protocols likely stems from a lack of consensus regarding the definition of what indeed constitutes "environmental enrichment". Some might define enrichment based on environmental complexity—that a more complex environment is more enriching; however, environmental complexity alone is not the whole story. Environmental enrichment, by most definitions, should exert a positive influence on the organism, setting enrichment apart from overtly stressful events that have a negative impact on the organism. Thus, enrichment must provide an overall benefit to the organism. Further confusion in the field also arises from the fact that some researchers compare EC rats only to pair-housed social condition (SC) rats or compare only IC with SC rats (see below for discussion of the appropriate control for enrichment). However, without discounting or dismissing the views of others studying environmental enrichment using different protocols, this paper outlines a theory that the mild daily stresses of the enriched lifestyle are adaptive and inoculate rats to produce protective preclinical phenotypes for addiction and depression.

2.1. What are the beneficial effects of environmental enrichment?

As mentioned above, environmental enrichment contains three basic components: novelty, exercise and social contact. Animals are group-housed in a large cage equipped with children's plastic toys, which are replaced and rearranged every day. In order to study the "preventive" effect of environmental enrichment, rats are usually raised in the enriched condition before exposure to drugs (in the case of addiction research) or stress (in the case of depression research). Environmental enrichment attenuates the reinforcing effects of addictive drugs and produces an antidepressant-like effect (Brenes et al., 2008; Brenes Saenz et al., 2006; Green et al., 2010; Laviola et al., 2008). In addition, environmental enrichment can be studied as a "treatment" model, in which rats are assigned

to either an isolated or enriched condition *after* they are exposed to drugs or stress, which has also been shown to produce adaptive consequences (Grimm et al., 2008; Solinas et al., 2008; Thiel et al., 2010). Below is an overview of the beneficial effects of environmental enrichment. To maintain focus, this hypothesis paper is predominantly centered on rodent research, although environmental enrichment has been studied in other species with success (Harlow, 1958; Harlow and Suomi, 1971; Nader et al., 2012; Solinas et al., 2010).

2.2. The protective addiction phenotype

Rats reared in an enriched condition exhibit lower basal locomotor activity than rats in the isolated condition, making interpretation of drug-stimulated locomotor data challenging. Despite this, the available evidence is fairly clear that EC rats show greater locomotor sensitivity to psychostimulants such as amphetamine and cocaine (Bardo et al., 1999; Bowling and Bardo, 1994a; Bowling et al., 1993; Smith et al., 2009) while at the same time showing reduced sensitization to repeated exposure (Bardo et al., 1995; Green et al., 2003; Smith et al., 1997). In the conditioned place preference (CPP) paradigm, a paradigm more relevant to addiction, Bowling and Bardo, and then Green and colleagues reported that enrichment produces enhanced CPP to both amphetamine and cocaine in rats (Bowling and Bardo, 1994b; Green et al., 2010). These results lead to the hypothesis that enrichment *increases* the risk for addiction; however, in the paradigm with the greatest face validity for addiction, the intravenous drug self-administration paradigm, the reinforcing effects of amphetamine, cocaine, ethanol, and methylphenidate are decreased by enrichment and the rats self-administer less of these drugs (Alvers et al., 2012; Bardo et al., 2001b; Deehan et al., 2007; Gill et al., 2013; Green et al., 2002, 2010; Stairs et al., 2006).

Enrichment also alters drug taking in treatment models. Exposure to enrichment *after* exposure to cocaine reduces locomotor activity, eliminates cocaine CPP and reduces cocaine-induced reinstatement of CPP, and decreases cocaine-seeking behavior during extinction and cue-elicited reinstatement (Chauvet et al., 2012; Ranaldi et al., 2011; Solinas et al., 2008; Thiel et al., 2009). Although cue-elicited reinstatement is reduced in the treatment model, enrichment does not alter cocaine-primed reinstatement, suggesting that enrichment reduces the salience of drug-associated environmental cues which could lead to an effective therapy for craving elicited by drug cues in humans (Thiel et al., 2009).

2.3. The protective antidepressant phenotype

Along with the protective addiction phenotype, environmental enrichment also produces a protective antidepressant-like phenotype. In humans, three of the hallmark symptoms of depression are anhedonia, social withdrawal and behavioral despair. Our prior research and others found that, compared to IC rats, EC rats consume more sucrose in a sucrose preference test, indicating decreased anhedonia-like behavior; longer grooming time in the social contact test, suggesting decreased social withdrawal; and greater mobility time in the forced swim test (FST), suggesting reduced "behavioral despair" (Brenes et al., 2008; Brenes Saenz et al., 2006; Green et al., 2010).

2.4. Anxiety

Similar to addiction- and depression-like behavior, multiple labs have demonstrated reduced anxiety-like behavior resulting from environmental enrichment. For example, EC rats display lower basal locomotor activity, yet increased distance traveled in the center of the arena in the open field test, indicating an anxiolytic effect (Urakawa et al., 2013). In addition, enriched rats and mice were found to spend more time in the open arms in the elevated plus maze (EPM), and showed lower amounts of defensive burying and less defensive behavior when in close proximity to a predator, also suggesting reduced anxiety (Friske and Gammie, 2005; Leal-Galicia et al., 2007; Roy et al., 2001). Enriched mice show reduced anxiety in response to social defeat stress, an effect that was abolished by lesioning the infralimbic region of the prefrontal cortex prior to environmental enrichment exposure (Lehmann and Herkenham, 2011), suggesting a role of the prefrontal cortex in anxiety and environmental enrichment.

However, not all are convinced that enrichment is anxiolytic. Our own research demonstrated greater sucrose neophobia in EC rats and more fecal boli in the cold-stress defecation test, both suggesting *increased* anxiety (Green et al., 2010). In addition, latency to ejaculation has been used as a measure of anxiety (Wallace et al., 2009), and EC rats exhibit increased latency to ejaculate, again suggesting increased anxiety (Urakawa et al., 2014). It is noteworthy that the last three tests (sucrose neophobia, cold-stress defecation, and latency to ejaculation) are not a function of exploratory activity in a novel environment. Because environmental enrichment involves extended exposure to novel environments whereas IC rats have very little to no experience in novel environments, this confounds the results of behavioral tests involving exploration of a novel environment. In addition, environmentally enriched rats show less social withdrawal than isolated rats, which may confound the results of social defeat tests on enriched animals (Green et al., 2010). Taken as a whole, the benefits of enrichment on anxiety-like behavior are not as clear as other areas, but further analysis of anxiety-like behavior in enriched animals is an interesting avenue for future experimentation.

2.5. Other disorders

Environmental enrichment has also been shown to have beneficial effects in rodent models of neurodegenerative diseases. For example, in a mouse model of Huntington's disease, enrichment delays the onset and slows disease progression by minimizing the loss of cerebral volume and by rescuing protein deficits (Hockly et al., 2002; Spires et al., 2004; van Dellen et al., 2000). Enrichment can also prevent neurodegeneration in C57BL/6 mice caused by a neurotoxin that causes Parkinson's disease-like symptoms in humans by regulating expression of the dopamine transporter (DAT) (Bezard et al., 2003). In addition, an increasing number of studies reported the beneficial effect of environmental enrichment in improving learning and memory in behavioral and molecular aspects of Alzheimer's disease (Bouet et al., 2011; Jankowsky et al., 2003, 2005; Levi et al., 2003; Wolf et al., 2006). A study on Tg2576 mice, a model of Alzheimer's, found that environmental enrichment counteracts the deleterious effects of chronic unpredictable stress in Alzheimer's disease progression (Jeong et al., 2011). Further, a recent proteomic study found that the microtubule-associated protein tau was upregulated in EC rats compared to IC rats (Fan et al., 2013a,b). That paper and two other proteomics papers also identified huntingtin, presenilin 1, tau and amyloid precursor protein as major upstream regulators for environmental enrichment (Fan et al., 2013a,b; Lichti et al., 2014). These results warrant further investigation of neurodegenerative disorders using the environmental enrichment paradigm.

2.6. Species differences

Although environmental enrichment has been studied extensively in rats, other species have garnered considerably less attention, save for the work of Harlow in monkeys described above (Harlow, 1958; Harlow and Suomi, 1971). However, the available

evidence from the primate literature suggests that enrichment is a protective factor for stress, as well as for addiction-related behavior (Harlow, 1958; Harlow and Suomi, 1971; Kozorovitskiy et al., 2005; Nader et al., 2012). There are, however, some important rat/mouse differences in the effects of environmental enrichment. For example, rats show the unusual phenotype where environmental enrichment increases responsiveness to stimulants such as cocaine or amphetamine in locomotor, CPP and neurochemical studies, while these same rats show decreased drug self-administration (Bardo et al., 1999, 2001a; Bowling and Bardo, 1994a; Bowling et al., 1993; Green et al., 2002, 2010); mice, on the other hand, show decreased sensitivity to stimulants after environmental enrichment (Solinas et al., 2009). Regardless, environmental enrichment produces a net benefit in addiction related behavior in both species (Solinas et al., 2010).

3. What is inoculation stress?

As described above, the environmental enrichment paradigm is a non-drug, non-surgical preclinical animal model useful for studying various psychiatric and neurological conditions. Environmental enrichment produces protective phenotypes in addiction and depression models, which are robust and replicable. The major question is *how* environmental enrichment can produce such robust individual differences in a wide range of behaviors associated with addiction, depression and anxiety and beneficial effects even for animal models of neurodegenerative diseases. Our hypothesis is that enriched rats undergo inoculation stress. In short, chronic very mild stress from living in a complex environment and interacting non-aggressively with conspecifics inoculates enriched rats against subsequent stressors and/or drugs of abuse.

Inoculation stress, described previously in human studies, is a process of developing resilience to future stressful events by first being exposed to mildly stressful experiences early in life (Dienstbier, 1989; Fox et al., 2006; Khoshaba and Maddi, 1999; Lyons et al., 2009; Meichenbaum, 2007; Parker et al., 2004; Rutter, 2006). Exposure to stress or adversity that toughens an individual is protective, much like a vaccination that exposes an individual to a non-harmful version of a disease in order to develop immunity to that illness for the future (Lyons et al., 2009; Rutter, 2006). For example, adults who are exposed to work stress as adolescents have fewer negative health effects from work-related stress as adults (Mortimer and Staff, 2004). Unlike a vaccine, however, inoculation stress does not protect only against a single disease, but toughens the individual in general and prepares them to cope with a variety of stressors later in life. For example, individuals that have successfully coped with some adverse events in adolescence have overall better mental health and are better able to cope with serious illness, spousal loss, or a major accident as adults (Khoshaba and Maddi, 1999; Lyons et al., 2009; Seery et al., 2013).

An important distinction to make is that inoculation stress is not simply exposure to any stress early in life, but rather having positive and adaptive responses to mild stressors is critical. Severe stress early in life often causes the individual to be more vulnerable to stress later in life whereas mild stress exposure with an adaptive response can protect the individual (Khoshaba and Maddi, 1999; Parker and Maestripieri, 2011). Stress that is inoculating conditions the individual, and provides specific coping strategies for exposure to future stressors, ultimately leading to resilience.

Stress inoculation has also been described in non-human primates and rodents. Squirrel monkeys and rodents exposed to a manageable stress early in life are less stress-reactive in the future (Lyons et al., 2009, 2010). In particular, environmental enrichment in adolescence is able to provide protection from the deleterious effects of subsequent stressors (Fox et al., 2006; Larsson et al., 2002; Lyons et al., 2009; Parker et al., 2004), providing the impetus for the hypothesis that environmental enrichment is a chronic mild stress environment leading to stress inoculation.

4. Allostasis and allostatic load

In trying to make sense of how mild/moderate stressors are adaptive yet severe stressors are maladaptive, it helps to frame the picture with respect to allostasis and allostatic load. For the purposes of this paper, the term “allostasis” will be used in its broadest sense, disregarding the narrow application of this term only to energy regulation (McEwen and Wingfield, 2010). Thus, allostasis is defined as the process of returning a dynamic system to its stable set point after a challenge to that system. In a conceptual sense, homeostasis is maintaining stability in a non-dynamic system while allostasis is regulating stability of a dynamic system.

The genome is chock full of allostatic mechanisms for maintaining stability in hundreds of dynamic systems. However, maintaining stability of a dynamic system is not without cost to the organism. This cost to the organism is termed “allostatic load” and can be paid in a currency as diverse as energy usage, ion concentrations (e.g. neuronal activity), or protein turnover. Regulatory systems have evolved to deal with allostatic load to a certain extent, but most systems are susceptible to “allostatic overload” if the demands on the system outpace the allostatic capacity. At that point, the system fails to maintain stability and pathology develops. In the arena of psychiatric conditions, allostatic overload is evident when severe stressors surpass the allostatic capacity of the person and induce pathological conditions such as post-traumatic stress disorder, major depression, addiction, and anxiety disorders (among others).

One thing that differentiates allostasis from homeostasis is that allostasis, by virtue of regulating a dynamic system, can *predict* future allostatic load and adjust its capacity accordingly in anticipation of that future load. For example, forcing the average person to run 12 miles will result in allostatic overload of many systems (energy, oxygen, joints, muscles) whereas the seasoned runner’s body has predicted the possibility of a 12 mile run and adjusted the allostatic capacity of these systems to match the high load. As a result, instead of being pathogenic, subsequent stressors can even be motivating to the individual, allowing them to thrive in adverse conditions. Thus, individual responses to the same stressful event can be highly variable, and the resulting effect on the individual depends on that individual’s allostatic capacity to handle stress.

Allostatic overload of stress response systems can lead to psychiatric disorders, but how can inoculation stress or exposure to mild stress become protective against developing psychiatric conditions? Unfortunately stress has garnered a negative connotation, making experiments on stress with humans and animal models sometimes ambiguous. In 1976, Hans Selye defined stress as “the nonspecific response of the body to any demand made upon it” (Selye, 1976). The term “stress” does not inherently specify whether the stimulus is adaptive (i.e. inoculation stress) or maladaptive (i.e. allostatic overload), but even in Selye’s own work it was often assumed that “stress” meant maladaptive stress. However, whether a stressor is positive or negative chiefly depends on the *allostatic capacity* of the individual. Most individuals exposed to stress are resilient to psychiatric conditions but those that are susceptible have a lower allostatic capacity for stress. Inoculation stress causes the organism to predict future stress and increase the allostatic capacity of the individual accordingly, providing resilience to subsequent stressors that might otherwise produce psychiatric conditions. Thus, environmental enrichment is hypothesized to increase allostatic load capacity from the repeated exposure to very mild stresses, inoculating against subsequent stressors.

Since allostatic capacity for stress is associated with psychiatric disorders, it is useful to assess allostatic load capacity for stress in rodents. There is a wide range of stressors from which to choose to preclinically examine allostatic load capacity. Mildly stressful stimuli include brief periods of restraint stress, mild footshock, brief exposure to temperature changes as in the cold stress-induced defecation paradigm, and handling by an experimenter (Gärtner et al., 1980; Green et al., 2010; Gregus et al., 2005; Rabasa et al., 2011b). Some severe stressors are long periods of immersion in cold water, long periods of food or water deprivation, and intense footshock (Rabasa et al., 2011b; Willner, 1997). One very severe stressor is social defeat by an aggressive conspecific (Covington and Miczek, 2005; Koolhaas et al., 1996; Müller et al., 2000). It is important to note that individual stressors can be considered mild or severe depending on duration and intensity. For example, brief maternal separation in rats is adaptive whereas lengthy maternal separation leads to allostatic overload and susceptibility in models of psychiatric conditions (Lyons et al., 2009; Sih, 2011). Thus, footshock, maternal separation, physical restraint, and temperature changes can be considered mild stressors or severe stressors.

Predictability also seems important; the so-called chronic unpredictable mild stress paradigm (CMS), despite the label of "mild", can be a strong enough insult to induce allostatic overload and prevent inoculation (see below). Therefore, evaluating the response of the rodent to various stressors can aid in gauging the allostatic capacity of the rodent (i.e. whether they are inoculated against future stressors).

5. Stress, addiction and depression

As mentioned in the previous section, severe stress can lead to various psychiatric disorders; therefore, understanding the consequences of adaptive and maladaptive stress is translationally relevant. Stress is not only implicated in conditions such as posttraumatic stress disorder, major depression, and anxiety disorders, but also drug use disorders. Severe stress in adolescence (such as being abused as a child) is associated with higher risk for alcoholism, substance abuse, depression, suicide attempts, obesity and poorer general health (Felitti et al., 1998; McEwen, 2000). Evidence suggests there is overlap in the underlying mechanisms for mental health disorders and drug use disorders (Levin et al., 2008; Worley et al., 2012), and psychological stress may be the common link. The environmental enrichment paradigm produces robust protective phenotypes for depression-like and drug abuse behaviors. Therefore, our hypothesis is not only does maladaptive stress increase the likelihood of psychological disorders and drug abuse, but also the protective effects of environmental enrichment may be due to adaptive responses to stress.

Regarding stress and depression, stress is the leading factor for both the development of and relapse to major depression (Hardeveld et al., 2013; Kendler et al., 1998, 1999; Morris et al., 2010). Stress in the workplace and major life events, such as the death of a spouse, can trigger depressive episodes and increase the risk of major depression (Heim et al., 1997; Tennant, 2001). Evidence suggests that alterations in the hypothalamo–pituitary–adrenocortical (HPA) axis, which is involved in coordinating the body's response to various stressors (i.e. managing allostatic load), are involved in depression. Cortisol is a glucocorticoid released by the adrenal cortex in response to environmental stimuli and individuals with higher cortisol reactivity to low stress conditions had more depressive symptoms over time than those with low cortisol reactivity (Morris et al., 2012). In order to study this phenomenon preclinically alterations in the hypothalamo–pituitary–adrenocortical axis should be evaluated.

Regarding addiction, stress is a leading factor contributing to relapse to drug use in humans (Pohorecky, 1991; Sinha, 2001; Sinha et al., 1999, 2006), an effect modeled by self-administration studies in rats (Ahmed and Koob, 1997; Erb et al., 1996). Stress exposure in humans, particularly to a severe stressor, significantly increases cocaine craving during abstinence (Pohorecky, 1991). In addition to contributing to relapse, there is increasing preclinical evidence that stress contributes to the initial development of addiction (Burke and Miczek, 2014; Covington and Miczek, 2005; Goeders, 2002; Piazza and Le Moal, 1998). For humans, stress increases the likelihood that someone will start smoking along with increasing the risk of relapse to cigarette smoking (Bruijnzeel, 2012). Additionally, exposure to stress increases cocaine craving (Sinha et al., 1999) and more stress-induced cocaine craving increases the likelihood of relapse in cocaine-dependent individuals (Sinha et al., 2006).

Beyond stress/addiction and stress/depression interactions, there is evidence linking addiction directly to depression (Levin et al., 2008; Worley et al., 2012). For example, individuals with major depression are more likely to smoke than the average person (Bruijnzeel, 2012). Major depression and substance use disorders are often comorbid in humans, and the symptoms are often more severe together than with only one disorder (Kessler et al., 2005; Pettinati et al., 2013). The rate of comorbidity of major depression with alcohol use disorders is 40.3%, and major depression with a drug use disorder is 17.2% (Pettinati et al., 2013). The high rate of comorbidity makes developing an effective treatment very complicated. If the mood disorder is solely substance-induced, controlling the drug use would solve both disorders, but if the mood disorder has some other etiology, then antidepressants may be required (Pettinati et al., 2013). Often treatment for individuals with these comorbid disorders is focused on one disorder or the other and disregards the fact that stress may underlie both disorders.

Depression and addiction phenotypes often go hand in hand not only in humans but also in rodents (Green et al., 2006, 2010; Green et al., 2008; Pettinati et al., 2013). For example, overexpression of a dominant negative inhibitor of CREB (inducible cAMP early repressor/ICER or a mutant CREB/mCREB) or knockdown of CREB in the NAc produces an antidepressant-like phenotype and also decreases cocaine self-administration in a similar manner to environmental enrichment (Green et al., 2006, 2010). Similarly, the transcription factor ΔFosB in the NAc is associated with stress and also cocaine-taking behavior (Vialou et al., 2010; Zhang et al., 2014). Thus, it is very difficult to tease apart addiction and depression phenotypes in humans and in rodent models. Therefore analysis of an animal model that addresses both disorders simultaneously, such as environmental enrichment, is very valuable. Further, the close ties between depression and addiction are hypothesized to explain how inoculation to stress can affect drug-taking behavior.

As a whole, the evidence linking stress, depression and addiction provides a plausible rationale for how the repeated mild stress of environmental enrichment can protect against addiction-related behavior.

6. Does cortisol/corticosterone equal stress?

Because stress is linked with psychological disorders and drug dependence disorders, assessing stress in preclinical models is translationally relevant but can prove to be difficult without a good objective measure of stress in animals. Often, measurements of plasma cortisol, or the rodent equivalent corticosterone (CORT), have been used as a measure of stress in a variety of experiments. CORT is the primary glucocorticoid released by the adrenal cortex as a final product of the HPA axis. The HPA axis is activated in response to environmental stressors and activation of this system releases CORT. As a result, many scientists use CORT as a de facto

indication of a subject's stress level. However, it is important to note that CORT does not equal stress. The following paragraphs will argue: (1) CORT levels fluctuate throughout the day independent of stress, (2) rewarding stimuli induce CORT release, (3) CORT induction is *attenuated* with chronic stress, (4) CORT itself is reinforcing and (5) behavioral responses to CORT administration alone do not mimic responses to stress. In addition, there are several caveats when attempting to extrapolate emotional and behavioral state from plasma CORT levels, not the least of which is that the mere act of acquiring a blood sample to measure CORT can be stressful itself, especially with high frequency sampling (Abelson et al., 2005). Therefore, evaluating stress in environmentally enriched animals based on CORT levels has contributed to differing hypotheses on whether enrichment or isolation is inherently stressful because of inconsistent findings of corticosterone levels between enriched and isolated animals (Konkle et al., 2010). However, this is not to say that CORT is not important, or that corticosterone is not involved in the beneficial effects of environmental enrichment. In fact, CORT and the HPA axis may be involved in the inoculation stress of environmental enrichment (see Section 8 below for elaboration). However, measured CORT levels do not provide a complete picture of the adaptive or maladaptive nature of the stress responses of an animal.

6.1. CORT levels fluctuate throughout the day

CORT measurements taken at different times during the circadian cycle will vary because CORT has a characteristic circadian rhythm. Regardless of stress level, CORT generally peaks as rats awaken just prior to the dark cycle and is lowest at the beginning of the light cycle (Allen and Kendall, 1967; Butte et al., 1976). The dark cycle is the period where the animals are awake and highly active versus the light cycle when the animals are mostly sleeping. Thus, if one were to use CORT as a de facto measure of stress, the circadian rhythm of CORT will likely produce confounding results depending on when blood is collected.

6.2. Rewarding stimuli induce CORT

Phasic CORT release subsequent to an environmental stimulus is generally assumed to be an indication that the animal is in a negative emotional state and that the stimulus had a negative impact. For example, social defeat, where a test subject is physically dominated by a more aggressive conspecific, is a noxious stressor and causes release of CORT in the defeated male (Buwalda et al., 2012). However, assumptions of a negative state are not always true. For example, sexual activity, a positive and rewarding stimulus, releases similar amounts of CORT as social defeat (Buwalda et al., 2012). Another stimulus, exercise, which is regarded as positive and rewarding, can also cause an increase in cortisol in humans (Buono et al., 1986; Deinzer et al., 1997; Rojas Vega et al., 2006). Voluntary exercise can also increase circulating CORT in Sprague–Dawley rats (Fediuc et al., 2006). In addition, rewarding drugs, including cocaine, cause CORT release (Moldow and Fischman, 1987; Torres and Rivier, 1992). Both rewarding and noxious stimuli cause alterations in CORT; therefore, CORT levels alone cannot differentiate between negative and positive stimuli.

6.3. CORT induction is attenuated with chronic stress

If CORT is a de facto measure of stress, one would expect repeated stress to increase CORT. Multiple studies have shown, however, that induction of CORT after a mild/moderate stressor attenuates with repeated exposure to the stressor in rats (Barnum et al., 2007; Carter et al., 2004; De Boer et al., 1990; Magarinos and McEwen, 1995; Mizoguchi et al., 2001; Natelson et al., 1988; Rabasa et al., 2011a). In humans, cortisol release also habituates with repeated exposures to the same stressor although there are individual differences in cortisol responses to stress (Deinzer et al., 1997; Gerra et al., 2001). This evidence suggests that repeated stress increases the allostatic capacity to future stressors, which is a possible mechanism for the inoculation stress underlying environmental enrichment effects.

6.4. CORT is reinforcing

Additional evidence that CORT is not the same as maladaptive stress is demonstrated by the fact that CORT itself has reinforcing properties. Rats will intravenously (Piazza et al., 1991) and orally self-administer CORT (Deroche et al., 1993), causing release of dopamine in the nucleus accumbens (NAc) (Graf et al., 2013). CORT injections also potentiate amphetamine self-administration at medium and high doses of amphetamine (10 and 30 μg/infusion) (Piazza et al., 1991). These experiments and others show that CORT is reinforcing at circulating levels similar to that released by mild stress (Piazza et al., 1991).

6.5. Responses to CORT differ from responses to stress

If CORT equals stress, then CORT administration should produce the same responses as stress. MacDougall and Howland found that rats injected with CORT versus rats exposed to 30 min of restraint stress (a mild stressor) had the same amount of circulating CORT, but only restrained rats showed changes in short- and long-term synaptic plasticity in the subiculum (MacDougall and Howland, 2013). Retana-Marquez et al. (1998) found that CORT injections were not able to mimic the behavioral effects of social defeat stress even at very high circulating plasma levels. Social defeat causes decreases in male sexual behavior and decreases in testosterone, whereas CORT injections do not (Retana-Marquez et al., 1998). Conversely, rats restrained for 6 h a day for 21 days did not show an increase in depression-like behavior in the forced swim test but rats injected with CORT did show an increase in depression-like behavior, suggesting that in some cases, elevated CORT can cause more maladaptive changes than mild restraint stress (Gregus et al., 2005). Thus, CORT and stress sometimes produce different behavioral effects, and CORT administration alone cannot reproduce the behavioral effects of stress; therefore CORT does not equal stress.

All told, it is clear that although stress usually releases CORT, the circulating level of CORT is not a direct measurement of stress level. Further, it is important to remember that animals in a chronically mild-stress environment show attenuated rather than potentiated CORT induction to stress or drugs. If CORT is not an adequate measure of stress, how can we determine if enriched rats are actually more stressed than isolated rats?

7. Are enriched rats really stressed?

The inoculation stress hypothesis of environmental enrichment proposes that enriched rats are repeatedly stressed. However, at first sight, it is exceedingly difficult to make this case. Young male Sprague–Dawley rats (unlike mice) typically establish dominance hierarchies through play behavior and, as long as there are no female rats in the vicinity, typically do not feel the need to challenge these hierarchies over time. Thus, in this rat enrichment utopia, fighting is rare, food is plentiful, space is expansive, and rats get all of the novelty, social contact (rats are social creatures), and exercise they desire. Additionally, it has repeatedly been proposed that enrichment is the "functional opposite of stress" (Fox et al., 2006; Solinas et al., 2010; Wright and Conrad, 2008). If true, how can one make the case that enriched rats are chronically stressed?

Table 1
Parallels between repeated stress and enrichment.

	Effect	Repeated mild stress	Environmental enrichment
Endocrine	Blunted CORT induction	Natelson et al. (1988), De Boer et al. (1990), Magarinos and McEwen (1995), Barnum et al. (2007), Rabasa et al. (2011b), Carter et al. (2004)	Stairs et al. (2011), Stairs and Bardo (2009), Skwara et al. (2012)
	Blunted ACTH induction	Gadek-Michalska and Bugajski (2003)	Skwara et al. (2012), Belz et al. (2003)
	Enlarged adrenals	Swanson and van de Poll (1983), Marti et al. (1993)	Mlynarik et al. (2004), Moncek et al. (2004)
	Blunted adrenaline release	Dobrakovova et al. (1990)	Moncek et al. (2004)
Neurobiology	ΔFosB accumulation in NAcc	Perrotti et al. (2004), Lobo et al. (2013)	Zhang et al. (2014), Lobo et al. (2013), Solinas et al. (2009)
	Attenuated immediate-early gene induction in NAcc	Shoji and Mizoguchi (2010) (cFos), Green et al. (2008) (ATF3),	Zhang et al. (2014), manuscript in preparation
Behavior	Higher sensitivity to locomotor activating effects of amphetamine and cocaine	Deroche et al. (1992), Lepsch et al. (2005)	Bowling et al. (1993), Bowling and Bardo (1994a,b), Smith et al. (2009), Green et al. (2010)
	Decreased stimulant self-administration	Matthews et al. (1996), Moffett et al. (2006), *however, see:* Carroll and Meisch (1984), Piazza et al. (1990), Goeders and Guerin (1994), Shaham and Stewart (1994), Miczek and Mutschler (1996), Kosten et al. (2000)	Bardo et al. (2001a,b), Green et al. (2002, 2010), Stairs et al. (2006), Thiel et al. (2009), Alvers et al. (2012), Puhl et al. (2012)
	Increased defecation under stress conditions	Jorge et al. (2010)	Green et al. (2010)
	Decreased locomotor activity to novelty	Cruz et al. (2012)	Bowling et al. (1993), Green et al. (2003, 2010)
Physiology	Heart rate returns to baseline more quickly after stress	Carter et al. (2004), Chen and Herbert (1995)	Sharp et al. (2002)
	Lower body weight	Harris et al. (2004)	Pena et al. (2009)

Although there are multiple good lines of evidence suggesting enrichment produces the functional opposite of stress (Fox et al., 2006; Solinas et al., 2010; Wright and Conrad, 2008), none of the reports gives a possible explanation for how enrichment produces this effect. The inoculation stress hypothesis of environmental enrichment outlined here posits that enrichment is a chronic mildly stressful condition that induces neuronal and neuroendocrine plasticity leaving enriched rats more resistant (i.e. greater allostatic capacity) to overtly stressful stimuli. Environmental enrichment exposes animals to novelty, social contact, and exercise and multiple studies have found that these variables cause stress-like responses. Acute voluntary exercise induces the secretion of CORT (Fediuc et al., 2006) and exposure to novelty will induce secretion of both CORT and adrenocorticotropic hormone (ACTH) in rats (Hennessy et al., 1979; Ostrander et al., 2006; Piazza et al., 1991; Larsson et al., 2002). Finally, rats housed together with conspecifics had higher circulating CORT levels than isolated rats suggesting that social contact also causes a stress-like response (Raz, 2013). However, in the absence of a truly reliable and objective measure of stress, one must rely on circumstantial evidence comparing the effects of enrichment with the effects of repeated mild stress (see Table 1).

As summarized in Table 1, there are numerous parallels between the effects of environmental enrichment and repeated mild stress, adding strength to the idea that enriched rats are chronically stressed. Due to the importance of stress as a contributing factor to depression and addiction (see above), the effects of chronic stress on the body have been studied in depth. Results of these studies have produced a clear picture of the endocrine, neurobiological and behavioral sequelae of chronic stress in humans and in rat models. Environmentally enriched animals have also been assessed for the same endocrine, neurobiological and behavioral effects. There is much evidence that repeated mild stress blunts CORT induction in response to subsequent stressors (Barnum et al., 2007; Carter et al., 2004; De Boer et al., 1990; Magarinos and McEwen, 1995; Natelson et al., 1988; Rabasa et al., 2011b) and environmental enrichment also results in blunted CORT induction to stress (Skwara et al., 2012; Stairs and Bardo, 2009; Stairs et al., 2011). Repeated exposure to severe stressors (i.e. those producing allostatic overload), such as social defeat stress, does not show reductions in CORT induction to subsequent stress (Barnum et al., 2007). Repeated stress also blunts stress-induced adrenocorticotropic hormone (ACTH) induction (Gadek-Michalska and Bugajski, 2003) and stress-induced release of adrenaline (Dobrakovova et al., 1990). Environmental enrichment also blunts ACTH induction (Belz et al., 2003; Skwara et al., 2012) and reduces stress-induced release of adrenaline (Moncek et al., 2004). In addition, enlarged adrenal glands have been found in environmentally enriched animals (Mlynarik et al., 2004; Moncek et al., 2004) and in animals exposed to repeated mild stress (Marti et al., 1993; Swanson and van de Poll, 1983). Environmental enrichment and repeated mild stress also both produce lower body weights (Harris et al., 2004; Pena et al., 2009) and following stress, the animal's heart rate returns to baseline more quickly (Carter et al., 2004; Chen and Herbert, 1995; Sharp et al., 2002).

Not only do environmental enrichment and repeated mild stress show the same endocrine consequences, they also show concordant neurobiological consequences in the nucleus accumbens. Environmental enrichment reduces induction of immediate early genes (IEGs) (Zhang et al., 2014), as does repeated stress (Alibhai et al., 2007; Green et al., 2008; Shoji and Mizoguchi, 2010). In contrast to other IEGs, environmental enrichment causes accumulation of basal ΔFosB protein in the nucleus accumbens (Lobo et al., 2013; Solinas et al., 2009), which also occurs in repeatedly stressed animals (Lobo et al., 2013; Perrotti et al., 2004).

Environmental enrichment also produces robust effects on behavior that show similarities to the behavior of repeatedly stressed animals. For example, enriched animals show increased defecation to a mild stressor (novel cage under cold conditions) (Green et al., 2010), and rats that were alternately restrained for 1 h or placed on a platform surrounded by water for 1 h a day for 5 days also show increased defecation (Jorge et al., 2010). Environmentally enriched animals are more sensitive to the locomotor activating effects of amphetamine (Bowling and Bardo, 1994a; Bowling et al.,

1993) and cocaine (Smith et al., 2009). Repeatedly stressed animals are also more sensitive to the locomotor activating effects of amphetamine and cocaine (Deroche et al., 1992; Lepsch et al., 2005). Despite being more sensitive to locomotor stimulants, environmental enrichment decreases spontaneous locomotor activity in response to a novel environment (Bowling et al., 1993; Green et al., 2003, 2010). After mild stress, animals also show a similar decrease in locomotor activity when placed in a novel environment (Cruz et al., 2012).

As described above and illustrated in Table 1, environmental enrichment and repeated mild stress have matching endocrine, physiological, neurobiological, and behavioral effects. Although this is circumstantial evidence, it supports the argument that environmentally enriched animals are in a state of chronic mild stress and this mild stress in adolescence inoculates against future stressors.

The mild stress of environmental enrichment, however, is distinct from the stress of paradigms such as the chronic mild stress (CMS) paradigm or the chronic unpredictable stress paradigm in that environmental enrichment constitutes predictable stress that produces adaptive responses. The chronic mild stress paradigm typically involves stressors such as food deprivation, water deprivation, brief exposure to another subject, lights on during the dark cycle, periods of titling the cage by 30 degrees, and long periods of wet bedding material which occur randomly throughout the week for several weeks (Murison and Hansen, 2001; Willner et al., 1987, 1992). The CMS procedure can reduce sucrose and saccharine preference after several weeks of this unpredictable stress exposure (Hatcher et al., 1997; Willner et al., 1987), an anhedonic-like effect that can be reversed by several weeks of treatment with a tricyclic antidepressant (Willner et al., 1987). However, the CMS paradigm does not typically have other depression-like effects, and under some conditions this paradigm can actually increase sucrose consumption, suggesting inconsistencies in the paradigm (Murison and Hansen, 2001). An inoculation stress interpretation of these inconsistent data would posit that the unpredictable nature of the CMS can elevate the "mild" stress to a level that induces allostatic overload and that the inconsistencies in anhedonic-like behavior are a function of degree. The CMS by Murison and Hansen (2001) may not have induced allostatic overload, thus producing an inoculating effect whereas the other two reports induced a more severe stress (Hatcher et al., 1997; Murison and Hansen, 2001; Willner et al., 1987). Indeed, Hatcher and Hansen reported only finding an anhedonic saccharin response when the CMS paradigm included food deprivation.

8. CORT as a possible mediator of the protective EC phenotype

The sections above argue that CORT is not the same as stress; however, that is not to say that CORT is irrelevant. In fact, CORT responses may contribute substantially to the environmental enrichment protective phenotypes. For example, the environmental enrichment protective addiction phenotype fits well with what is known of the influences of CORT on stimulant self-administration. As mentioned above, CORT itself can be self-administered by rats (Deroche et al., 1993; Piazza et al., 1991), but there also exists evidence that CORT plays a significant role in stimulant self-administration. For example, higher CORT induction was associated with greater self-administration of low unit doses of cocaine regardless of whether the rats were stressed with contingent footshock, noncontingent footshock or no footshock (Goeders and Guerin, 1996b). Next, acquisition of cocaine self-administration can be completely blocked by bilateral adrenalectomy, partially reduced by pharmacological inhibition of corticosterone release by metyrapone in rats, and self-administration can be partially recovered by adding CORT to the drinking water (Goeders and Guerin, 1996a). Given that stimulants induce CORT release and blocking that release blocks self-administration, it is likely that the *amount* of CORT release from a stimulant determines the ability of low doses of that stimulant to engender or maintain self-administration. Blunted CORT release from stimulants in EC rats (Stairs and Bardo, 2009) could be the underlying molecular mechanism whereby inoculation stress produces the protective EC addiction phenotype. Further investigations are warranted to test this hypothesis.

9. Stress influences on self-administration

As discussed above, acute stress in humans is a major factor in relapse to addiction, so it is not surprising that acute stress in rodents produces reinstatement of cocaine seeking (Erb et al., 1996). However, the question at hand is how prior stress (i.e., not during or immediately before the session) affects subsequent stimulant self-administration. The logic in the above sections suggests that inoculation stress blunts CORT induction and that a blunted CORT response leads to less stimulant self-administration. Hence, one would predict that prior repeated mild stress (i.e. inoculation stress) would decrease drug self-administration. Two reports show that rats exposed to short-term maternal separation stress as pups later show reduced acquisition of cocaine self-administration at low unit doses (Matthews et al., 1996; Moffett et al., 2006). Despite these reports however, there are several reports showing that repeated stress *increases* stimulant self-administration (Carroll and Meisch, 1984; Goeders and Guerin, 1994; Kosten et al., 2000; Miczek and Mutschler, 1996; Piazza et al., 1990; Shaham and Stewart, 1994). Multiple factors could account for this discrepancy. First, the stressors in some of these papers are severe stressors that would exceed the allostatic capacity of the rats. Second, it is possible (even likely) that inoculation stress is most pronounced in very young animals (as with maternal separation and environmental enrichment). Third, it is possible that many other factors affect self-administration and that one or more of these factors are at play in some of these experiments. Regardless, if the inoculation stress hypothesis of environmental enrichment is correct, one would predict that environmental enrichment would decrease stimulant self-administration, which is undoubtedly the case (Alvers et al., 2012; Bardo et al., 2001b; Green et al., 2002, 2010; Puhl et al., 2012; Stairs et al., 2006; Thiel et al., 2009). In any case, the fact remains that EC rats have blunted CORT responses, blunted CORT responses are associated with less self-administration, and EC rats self-administer stimulants less readily than IC rats which supports the inoculation stress hypothesis.

10. What is the best control for enrichment?

An important problem in the enrichment field is the difficulty of being able to compare results between labs because of inconsistencies in enrichment protocols and the use of different control groups. Environmental enrichment is a compound manipulation whereby rats are chronically exposed to novelty, social contact, and exercise. The most rigorous scientific approach would be to study each aspect individually and then in combination. For example, it would be nice to know the relative contributions of social contact vs. object novelty vs. exercise, and if the combination of these factors is redundant, additive or synergistic. However, it is not possible to fully separate these aspects because social interaction is a form of novelty and greatly increases activity (i.e. exercise). In addition, this approach would entail studying eight different conditions, and we as scientists have an ethical obligation to reduce as much as possible the number of animals used in biomedical research (Council, 2011).

Additionally, as the number of conditions increases, there rapidly comes a point of diminishing returns where the cost (in money and time) of running an increasing number of conditions exceeds the small incremental benefit of the knowledge gained. Thus, the number of conditions must be limited. The fact that novelty, social contact and exercise all fall under the umbrella term "environmental enrichment" presupposes some commonality among the three constituents of enrichment. Indeed, each of these factors is rewarding to rats, and each releases dopamine in the nucleus accumbens, a critical brain region involved in stress, addiction, and depression (Greenwood et al., 2011; Louilot et al., 1986; Rebec et al., 1997). Accordingly, the many different conditions can now be reduced to as few as two: environmental enrichment and the appropriate control group.

Identifying the appropriate control group for cocaine administration is easy—an injection with no cocaine. Logic would dictate that the appropriate control for environmental enrichment (composed of novelty, social contact and exercise) would be a group with the absence of novelty, social contact, and exercise (i.e. isolation). Because pair housing is a form of enrichment (Council, 2011), comparing EC to pair-housed "control" rats would be akin to comparing a 20 mg/kg cocaine group to a 10 mg/kg "control". The problem is that "standard" laboratory housing for rats is two per cage in most research laboratories, and as such, these pair-housed rats are viewed by many scientists to constitute the "normal", or control condition. From this viewpoint, instead of seeing a continuum of enrichment ranging from isolation to pair-housed to full enrichment, environmental enrichment is seen as one manipulation (compared to pair-housed rats) and environmental isolation is seen as a different kind of manipulation.

At first sight, the case for isolation being a different kind of manipulation might seem to have merit. The case that many researchers make is that isolation itself is a stressor, and as such should not be used as a control. Indeed, many studies have shown that maternal separation (isolating pups from dam) and neonatal isolation (isolating pups from dam and other pups) are significant stressors, evoking ultrasonic vocalizations and inducing CORT release in pups (Hennessy and Weinberg, 1990; Kehne et al., 1991; Kuhn et al., 1990; Levine et al., 1991; McCormick et al., 1998; Viau et al., 1996). In addition, acute isolation of group-housed rats also induces CORT, which is taken as a clear indication of stress (Takatsu-Coleman et al., 2013). Many researchers thus make the leap of considering isolation rearing a condition of chronic stress, citing large CORT induction from acute stress as evidence. However, the inoculation stress hypothesis states that enriched animals are in a state of chronic very mild stress. As described above, *blunted* CORT induction is a sign of chronic stress, which is seen in EC rats and chronic mildly stressed animals alike. Table 1 further illustrates the many other signs of chronic stress that EC rats show that IC rats do not show. It is important to make the distinction that exhibiting a greater response to a stressor is not the same as being chronically stressed—quite the opposite. The isolated animals essentially have a lack of daily stimulation (i.e. stress) and therefore show a greater response to stress than EC rats, which are constantly stimulated (i.e. stressed) and therefore show a lesser response to subsequent stress.

Arguments frequently used in favor of pair-housed controls over isolated controls is that the IC group is not a "natural" condition, nor a "normal" condition, and has less "translational relevance" than pair-housed rats. Pair-housing rats in a laboratory is certainly not more translationally relevant than any other housing condition. The only place it is normal for two humans to be confined in the same small space is in prison. As for "normal", even wild rats are social animals and are found in groups rather than pairs that stick together constantly. Regardless, is a control group itself supposed to be "normal"? In the case of a pharmacological control group, would it be "normal" for a human to take an injection of saline rather than a drug? A control group should be the lack of a manipulation, but the pair-housed or social condition contains some of the variables of enrichment, namely social interaction and elements of exercise or play, and therefore is an intermediate level of enrichment capable of producing some behavioral effects of full enrichment, but not all (Bardo et al., 2001b; Green et al., 2010; Rosenzweig, 2003; Zakharova et al., 2012). For as described above in the inoculation stress hypothesis, environmental enrichment is a combination of exercise, novelty, and social contact with conspecifics, all of which are mild stressors resulting in inoculation against future stressors. Neither social interaction, novelty, nor any other single variable can account for all of the effects of enrichment (van Praag et al., 2000). However, the goal in using the environmental enrichment paradigm is not to tease apart the different aspects of enrichment or different gradations of enrichment but rather to determine differences between enrichment and the lack of enrichment to find the molecular determinants of the resilience to addiction and depression. Therefore, in our opinion in light of the inoculation stress hypothesis, the isolated condition is the correct control for enrichment and the inclusion of an intermediate group such as the social condition is unnecessary.

11. Conclusions

The inoculation stress hypothesis is an under-appreciated framework for understanding many of the complexities of stress and an organism's response to that stress. This hypothesis also has utility as a scaffold for which to build other novel hypotheses concerning susceptibility and resistance to psychiatric conditions such as addiction and major depression. Accordingly, application of the inoculation stress hypothesis to the environmental enrichment paradigm helps clarify the nature of nurture (i.e. role of environment) and its contribution to the resilience to addiction- and depression-related behavior. Future research designed from a better understanding of stress and environment will help to identify novel targets for the treatment of addiction and depression. Current research is already making headway (Fan et al., 2013a,b; Pavlovsky et al., 2013).

Instability of default mode network connectivity in major depression: a two-sample confirmation study

T Wise[1,2,6], L Marwood[1,2,6], AM Perkins[1,2], A Herane-Vives[1,3], R Joules[4], DJ Lythgoe[4], W-M Luh[5], SCR Williams[2,4], AH Young[1,2], AJ Cleare[1,2,7] and D Arnone[1,2,7]

Major depression is associated with altered static functional connectivity in various brain networks, particularly the default mode network (DMN). Dynamic functional connectivity is a novel tool with little application in affective disorders to date, and holds the potential to unravel fluctuations in connectivity strength over time in major depression. We assessed stability of connectivity in major depression between the medial prefrontal cortex (mPFC) and posterior cingulate cortex (PCC), key nodes in the DMN that are implicated in ruminative cognitions. Functional connectivity stability between the mPFC and PCC over the course of a resting-state functional magnetic resonance imaging (fMRI) scan was compared between medication-free patients with major depression and healthy controls matched for age, sex and handedness. We tested replicability of the results in an independent sample using multi-echo resting-state fMRI. The primary sample included 20 patients and 19 controls, while the validation sample included 19 patients and 19 controls. Greater connectivity variability was detected in major depression between mPFC and PCC. This was demonstrated in both samples indicating that the results were reliable and were not influenced by the fMRI acquisition approach used. Our results demonstrate that alterations within the DMN in major depression go beyond changes in connectivity strength and extend to reduced connectivity stability within key DMN regions. Findings were robustly replicated across two independent samples. Further research is necessary to better understand the nature of these fluctuations in connectivity and their relationship to the aetiology of major depression.

Translational Psychiatry (2017) **7,** e1105; doi:10.1038/tp.2017.40; published online 25 April 2017

INTRODUCTION

Depression is a common illness with substantial negative consequences for sufferers and society.[1,2] A better insight into neurobiological changes contributing to symptom generation is a research priority to improve diagnosis and treatment.[3]

Neuroimaging has enhanced our understanding of the neurobiological mechanisms underlying depressive symptoms[3–6] by identifying potential alterations in the structural and functional brain networks.[4,7] The default mode network (DMN) is one system that has attracted great research interest in major depression. One reason for this relates to its importance in the generation of self-referential thoughts, negative rumination and depressive symptoms.[8] A recent meta-analysis of static connectivity studies in major depression demonstrated hyperconnectivity within the DMN and between the DMN and fronto-parietal systems.[4] Within the DMN, the subsystem connecting the medial prefrontal cortex (mPFC) with the posterior cingulate cortex (PCC) is considered pivotal in generating affective, self-directed judgements and thoughts.[8,9] Although heightened static functional connectivity has been shown in major depression within this subsystem in association with a ruminative cognitive style,[4,10] there is uncertainty about its functional temporal stability. Connectivity variability is a plausible mechanism in major depression to explain brain responses associated with cognitive demands and processing of emotions.[11]

There is, however, little dynamic functional connectivity research published to date[11,12] with only one study in major depression.[13] This study showed increased variability in connectivity within the DMN between the mPFC and the insula, which correlated with a ruminative thinking style and coexisted with decreased variability between the mPFC and the parahippocampal gyrus.[13] No effect was found between the mPFC and PCC in this study, despite these being crucial in the generation of self-directed negative affective cognitions, potentially due to the less powerful whole-brain analysis method used.

Hence, we specifically evaluated temporal connectivity variability between the mPFC and the PCC, a subsystem within the DMN, given its relevance to ruminative cognitions associated with depression.[8,9] Kaiser *et al.*[13] observed increased connectivity variability between the mPFC and insula, part of the 'salience network' that is known to influence synergistically this DMN subsystem when processing internally generated salient information,[14] correlating with levels of rumination. Based on this finding that connections related to rumination show increased variability, we hypothesized increased connectivity variability in major depression between the mPFC and the PCC, correlating

with ruminative cognitions. We tested this hypothesis first in a primary sample of medication-free participants with major depression selected to be free from psychiatric comorbidity. We then validated the robustness of this result by replicating the findings in an independent clinical sample. As a further test of the stability of the results in the presence of significant clinical heterogeneity, the validation sample included patients with major depression and comorbid anxiety disorders. Furthermore, the robustness of the neuroimaging results to non-neural artefacts was ensured by utilizing multi-echo functional magnetic resonance imaging (fMRI), a recent development that is superior to traditional de-noising methods.[15]

MATERIALS AND METHODS

Participants

The right-handed participants aged 18–65 were recruited from the local community using online advertisements[16] and waiting lists of local psychological therapy services. Given the novelty of the method, we were unable to determine an expected effect size *a priori*. However, the sample size was chosen to be consistent with other studies in the area and we used a validation sample to ensure our results were robust. All patients met Diagnostic and Statistical Manual for Mental Disorders IV criteria for unipolar major depression (current or recurrent episode), as determined by clinical interview based on the Mini International Neuropsychiatric Interview.[17] In the primary sample, comorbid conditions were excluded. For the validation sample, comorbid anxiety disorders were allowed alongside major depression. Depression severity was assessed with the Montgomery–Åsberg Depression Rating Scale[18] and a score $\geqslant 18$ was required for inclusion. Raters for both samples were trained on an independent sample of patients and demonstrated high inter-rater reliability (Intraclass correlation coefficient = 0.96, $P = 0.004$). The severity of anxiety symptoms was assessed using the Hamilton Depression Rating Scale 17 anxiety/somatization factor items (anxiety subscale)[19,20] and handedness with the Edinburgh Handedness Inventory.[21] Trait rumination was assessed using the Rumination Response Scale (RRS),[22] a 22-item self-report measure. Patients were not receiving any form of treatment, psychological or pharmacological, at the time of scanning and were medication-free for $\geqslant 2$ weeks ($\geqslant 4$ weeks for fluoxetine) before MRI scanning. No subjects had been receiving treatment with medication requiring a longer washout period. Healthy controls were assessed to exclude personal and familial (first-degree relatives) psychiatric history. Exclusion criteria for all the subjects included history of head injury, illicit substance use in the preceding two months, unstable medical illness, any treatment with potential psychotropic properties or interference with participants' safety or data interpretation, pregnancy or other contraindications for scanning.

Ethics approval

The research was approved by the local ethics committee. The subjects provided written informed consent and were compensated financially for participating.

fMRI acquisition

The data for each sample were acquired on two identical GE MR750 3-Tesla scanners with 12-channel radiofrequency head coils. The participants fixated on a cross with their eyes open for the scan duration. For the primary sample, a 6-min resting-state scan using a T2*-weighted echo-planar imaging sequence was acquired (repetition time = 2000, echo time = 30 ms, field of view = 22.1 cm, flip angle = 75°, 39 slices, resolution = 3.3 mm^3). The cardiac signals and respiratory information were also recorded. For the validation sample, the data were acquired using an 8-min multi-echo sequence (repetition time = 2300 ms, echo time = 12.7/31/48 ms, field of view = 24 cm, flip angle = 90°, 33 slices, resolution = $3.75 \times 3.75 \times 4.2$ mm). An identical high-resolution T1-weighted structural image was acquired for both the samples.

fMRI preprocessing

The data were pre-processed with custom Nipype (http://nipy.org/nipype/) scripts, using tools from SPM12 (http://www.fil.ion.ucl.ac.uk/spm), FSL 5.0.9 (http://fsl.fmrib.ox.ac.uk/), AFNI (https://afni.nimh.nih.gov/afni/), along with custom code (available upon request). The first four volumes of the functional series were discarded to allow for equilibration effects. Slice timing correction was performed and the images were realigned and co-registered to the structural image using the normalized mutual information method in SPM12. For the primary sample, physiological signals (cardiac and respiratory) were regressed from the data using AFNI's RETROICOR[23] tool. For the validation sample, multi-echo data were pre-processed using the multi-echo independent component analysis tool in AFNI[15] to isolate components in the signal representing true blood oxygen level dependent (BOLD) signal. This was used in place of RETROICOR as it has been shown to be a more effective method of de-noising.[15] The remaining processing steps were identical for both samples for consistency. Six motion parameters (three translation, three rotation, determined from the middle echo image for the validation sample) plus time series extracted from the white matter and cerebrospinal fluid regions were regressed out of the data. Data were then temporally filtered from 0.008 to 0.09 Hz before being demeaned, de-trended and smoothed with a 6 mm full width at half maximum kernel. Thus, preprocessing for both samples was identical except for the method of de-noising used.

Motion scrubbing

As even minimal head motion can affect correlations calculated from resting-state data when not controlled for,[24] time points exhibiting excessive motion were scrubbed from the BOLD time series.[24] Motion at each time point was assessed using root mean square (RMS) intensity difference between volumes (REFRMS) and DVARS[24] as calculated using the FSL motion outliers tool with default thresholds. As directly removing time points would affect the length of the sliding window, and hence dynamic connectivity estimates, we instead interpolated time points showing substantial motion using third-order b-spline interpolation. To compare motion estimates between samples, we used both total distance travelled and framewise displacement.[24] All the analyses were performed on the scrubbed, pre-processed data.

Region of interest definition

We performed group canonical independent component analysis,[25] implemented in Nilearn and using 20 clusters, to identify the DMN components. The clusters centred on the posterior cingulate and mPFC regions in the DMN component were used to create regions of interest (ROIs) for the connectivity variability analysis. A 10 mm diameter sphere was created based on the peak of each cluster in the independent component analysis, and mean time series were extracted from each of these ROIs. This procedure was performed independently for the two samples to identify sample-specific ROIs. These ROIs were used in place of the entire cluster to provide a more consistent signal and avoid contamination from surrounding areas. To ensure that results were specific to these regions rather than being a global pattern, or caused by non-neural factors, we performed a negative control analysis between these regions and a 10 mm spherical ROI in the medial primary motor cortex (Montreal Neurological Institute coordinates = −1, −8, 63), a region not previously linked to depression.

Sliding window correlation analysis

The sliding window analysis was performed using custom Python (https://www.python.org/) scripts. The data were split into 40 s Gaussian moving windows, staggered by one repetition time, created using a Gaussian kernel with a standard deviation of 8 s (see Supplementary Methods for a detailed discussion of the sliding window methodology). This time period has been shown to be appropriate for characterizing dynamic functional connectivity[26] and provides a fine-grained picture of temporal changes in connectivity. For each window, correlations were computed between variance-normalized time series from the two regions using Pearson correlations, the results of which were then transformed to *Z*-scores. The variability of these correlations was calculated as their standard deviation, and subjects with outlying correlation variability values (±3 standard deviations from the mean) were removed. We also calculated the static functional connectivity strength between these regions using the entire, non-windowed time series to understand the relationship between static and dynamic functional connectivity. Further statistical analyses were performed using R.[27] All the group comparisons and correlations were adjusted for age, sex and head motion (total distance travelled), and were corrected for the number of comparisons (mPFC–PCC and two negative controls) using false discovery rate correction.

We assessed relationships between functional connectivity variability and clinical measures including depression and anxiety severity scores, time since illness onset and RRS in Pearson partial correlations.

Voxel-based morphometry

We also compared grey matter volumes in the chosen ROIs between patients and controls using voxel-based morphometry to examine the co-existence of volumetric changes that may explain changes in connectivity. High-resolution T1-weighted structural images (repetition time = 7.31 ms, time to echo = 3.02 ms, 256 × 256 matrix, 196 slices, voxel size = 1.2 × 1.05 × 1.05 mm, for both the samples) were pre-processed using voxel-based morphometry in SPM12 (*www.fil.ion.ucl.ac.uk/spm*) for both the samples. Images were segmented into different tissue types and processed with DARTEL[28] before being normalized to Montreal Neurological Institute space. The modulated grey matter images were then smoothed with an 8 mm full width at half maximum Gaussian kernel. Grey matter volume was next compared between groups within the same mPFC and PCC regions of interest used in the functional connectivity analysis with a two-sample *t*-test. A cluster-defining voxelwise threshold of $P < 0.001$ uncorrected was used, with a clusterwise threshold of 0.05 false discovery rate corrected. Total grey matter volume was also calculated based on the segmented maps created in SPM (thresholded at grey matter volume probability >0.5) and compared between the groups.

RESULTS

Participants

Twenty patients with unipolar major depression in the primary study and 19 in the validation study were sex and age matched with 19 healthy controls in the primary sample and 20 in the validation sample (Table 1). Three and nine subjects were recruited through psychological therapy services in the primary and validation samples, respectively, while the remaining participants were recruited from the community. A healthy participant from the validation sample was removed from the analyses due to outlying connectivity variability values. Figure 1 shows coordinates for the selected ROIs.

Connectivity variability in major depression

Connectivity variability, expressed as the standard deviation of connectivity strength between the mPFC and the PCC (Figure 2), was significantly greater in patients with major depression versus healthy controls ($t(37) = 2.56$, $P = 0.044$, $d = 0.82$). This effect was successfully replicated in the validation sample ($t(36) = 2.53$, $P = 0.045$, $d = 0.82$) supporting the coherence of the model in identifying consistently greater connectivity variability across samples irrespective of clinical heterogeneity.

There were no group differences in connectivity variability in either sample between the mPFC and primary motor cortex, chosen as a negative control region (primary sample: $t(37) = 0.79$, $P = 0.44$, validation sample: $t(36) = 1.85$, $P = 0.22$), or between the PCC and primary motor cortex (primary sample: $t(37) = 1.76$, $P = 0.17$, validation sample: PCC: $t(36) = 0.63$, $P = 0.99$), suggesting that results did not reflect global instability. No differences in static connectivity strength between mPFC and PCC were found between patients and controls in either sample (primary sample: $t(37) = 0.33$, $P = 0.74$, $d = 0.11$, validation sample: $t(36) = 0.73$, $P = 0.47$, $d = 0.24$).

Connectivity variability and cognitive style

A positive correlation of RRS with connectivity variability was noted in the validation sample ($r(14) = 0.51$, $P = 0.045$, Figure 3), and not the primary sample ($r(15) = 0.18$, $P = 0.48$). The relationship did not remain significant in a pooled analysis with both groups combined and sample as a covariate ($r(34) = 0.30$, $P = 0.075$). We did not find significant correlations between RRS scores and static connectivity strength in either sample (primary sample: $r(15) = 0.31$, $P = 0.22$, validation sample: $r(14) = -0.13$, $P = 0.62$).

Table 1. Samples clinical characteristics

	Major depression	*Healthy control*	P
Primary sample			
n	20	19	
Age, years	29.55 (6.59)	30.05 (6.71)	0.81
Male/female	2, 18	2, 18	1
MÅDRS	27.25 (4.24)	0.95 (1.39)	< 0.001
HDRS anxiety subscale	4.95 (2.48)	0.21 (0.42)	< 0.001
RRS	56.00 (10.23)	29.67 (6.44)	< 0.001
Time since illness onset, years	6.35 (6.41)	—	—
Comorbid diagnoses	None	—	—
Hospitalizations	0	—	—
Number of episodes	1.5 (1.25)	—	—
Validation sample			
n	19	19	
Age, years	32.34 (10.62)	31.91 (10.30)	0.90
Male/female	7, 12	6, 13[a]	0.73
MÅDRS	30.74 (7.31)	1.37 (1.86)	< 0.001

Abbreviations: GAD, generalized anxiety disorder; HDRS, Hamilton Depression Rating Scale (17 item); MÅDRS, Montgomery-Åsberg Depression Rating Scale; OCD, obsessive compulsive disorder; PD, panic disorder; PTSD, post-traumatic stress disorder; RRS, Ruminative Response Scale; SAD, social anxiety disorder. [a]Demographics for the validation sample represent the 19 healthy controls included in the final analysis. The samples did not differ on depression severity ($t(37) = -1.83$, $P = 0.07$). The validation sample had a significantly higher anxiety score ($t(37) = 3.45$, $P = 0.001$), time since illness onset ($t(37) = 2.62$, $P = 0.01$) and RRS score ($t(37) = 3.51$, $P = 0.001$) than the primary sample. Values are reported as mean (standard deviations) for all variables except number of episodes where due to skewed data we report median (interquartile range).

Correlations with clinical variables

Correlations between connectivity variability and depressive symptom severity were not significant (primary sample: $r(15) = 0.37$, $P = 0.14$, validation sample: $r(14) = 0.23$, $P = 0.40$). The same pattern of results was observed between correlation variability and anxiety symptoms scores, as measured by the anxiety subscale of the Hamilton Depression Rating Scale (sample A: $r(15) = 0.11$, $P = 0.66$, sample B: $r(14) = -0.23$, $P = 0.39$). The time since illness onset was not significantly correlated with connectivity variability in either sample (sample A: $r(15) = 0.25$, $P = 0.33$, sample B: $r(14) = 0.16$, $P = 0.55$).

Grey matter volumes

There were no differences between groups in grey matter volume in the chosen regions of interest (no significant clusters at $P < 0.001$, false discovery rate corrected). There were also no differences in the total grey matter volume between groups (primary sample: $t(37) = 1.43$, $P = 0.16$, validation sample: $t(36) = 0.79$, $P = 0.43$).

Head motion

There were no significant differences in the total distance travelled between the patients and controls in the primary sample

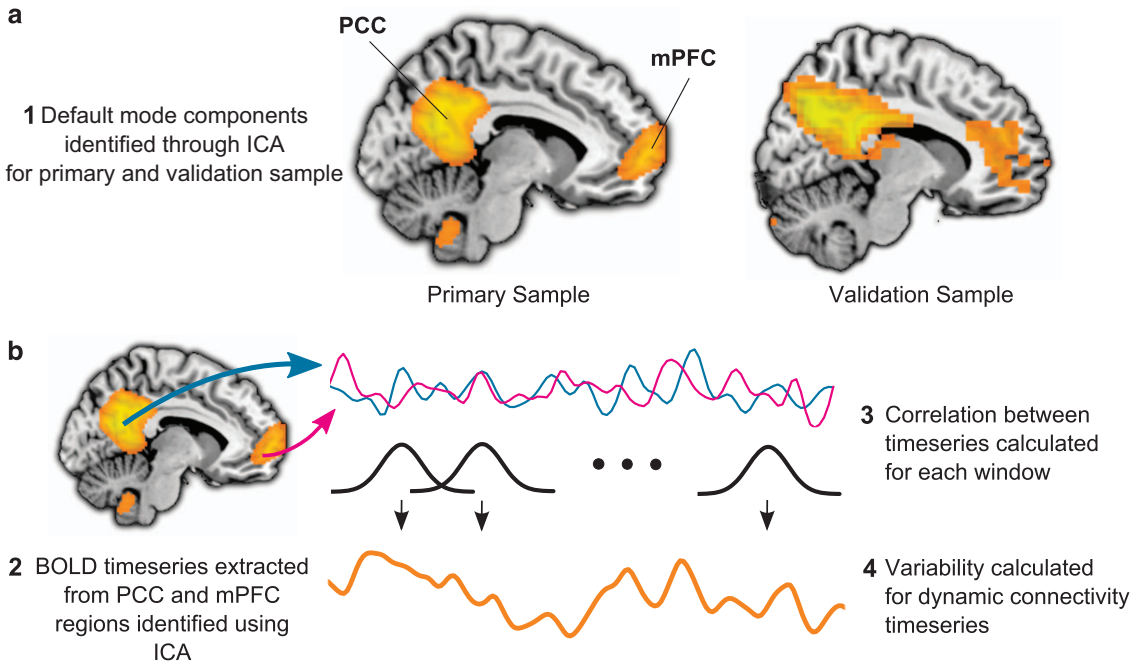

Figure 1. Illustration of the dynamic functional connectivity analysis method. In the primary sample, sample-specific Montreal Neurological Institute (MNI) coordinates for the posterior cingulate cortex (PCC) were 2, −62, 22 and for the medial prefrontal cortex (mPFC) 4, 60, 0. In the validation sample, MNI coordinates were 6, −44, 11 and 2, 60, −4, respectively. (**a**) Default mode network (DMN) components for each sample identified using group independent component analysis (ICA), showing clusters in the mPFC and PCC. (**b**) Illustration of the dynamic functional connectivity method. BOLD, blood oxygen level dependent.

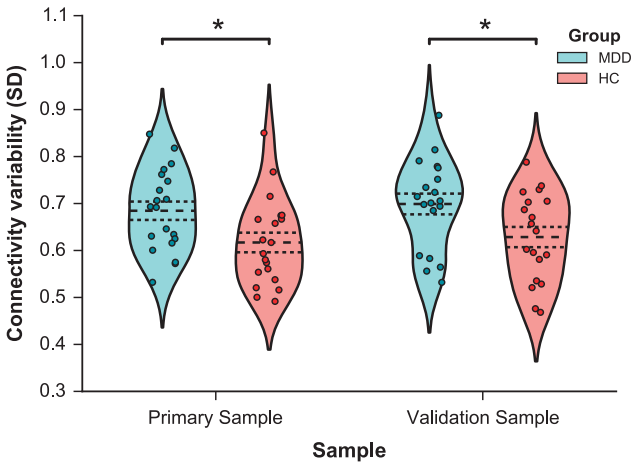

Figure 2. Variability in connectivity strength for patient and healthy control groups in both samples. Plots represent the distribution of data for each group, along with individual data points. Dashed lines represent means and standard errors. *$P < 0.05$ ($P = 0.044$ for the primary sample and $P = 0.048$ for the validation sample). HC, healthy controls; MDD, major depressive disorder.

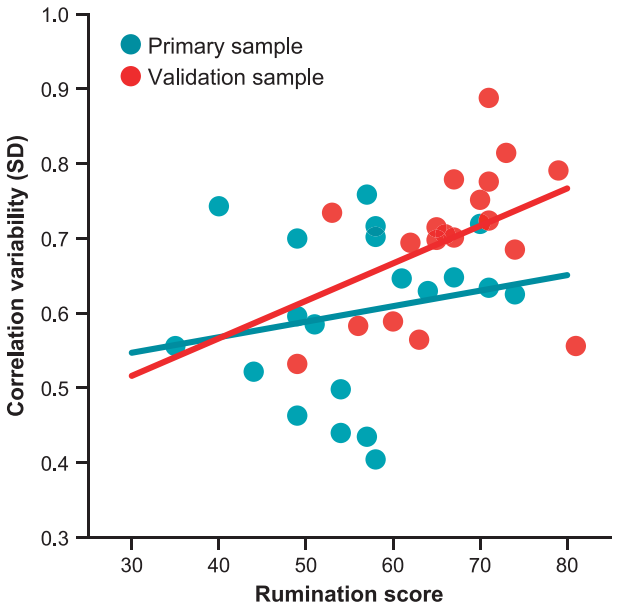

Figure 3. Correlation between connectivity variability and ruminative response style (RRS) score in major depression in the primary and validation sample. RRS, Rumination Response Scale.

($t(37) = -1.31$, $P = 0.20$) or the validation sample ($t(36) = 0.56$, $P = 0.58$). When looking at framewise motion measures, there were no significant differences between the groups in mean framewise displacement (primary sample: $t(37) = 0.88$, $P = 0.38$, validation sample: $t(36) = 0.26$, $P = 0.80$) or maximum displacement (primary sample: $t(37) = 0.42$, $P = 0.68$, validation sample: $t(36) = 1.48$, $P = 0.15$). There was also no significant difference between groups in the number of interpolated time points (primary sample: $U(37) = 173$, $P = 0.64$, non-parametric test used due to non-normally distributed data, validation sample: $t(36) = 1.60$, $P = 0.12$), or in the thresholds used for detecting outlying time points for either the primary sample (REFRMS: $t(37) = -0.14$, $P = 0.89$, DVARS: $t(37) = 0.42$, $P = 0.68$) or the validation sample (REFRMS: $t(36) = 0.67$, $P = 0.51$, DVARS: $t(36) = 0.71$, $P = 0.48$).

There were also no significant correlations in the validation sample between rumination scores and total distance travelled ($R(17) = 0.13$, $P = 0.59$), mean displacement ($R(17) = -0.09$, $P = 0.70$), maximum displacement ($R(17) = 0.17$, $P = 0.48$), or the number of interpolated time points ($R(17) = 0.11$, $P = 0.66$), indicating that the observed relationship between connectivity variability cannot be explained by motion. There were no significant relationships between thresholds used to detect outlying time points and rumination scores (REFRMS $R(17) = 0.11$, $P = 0.65$, DVARS: $R(17) = 0.35$, $P = 0.15$).

DISCUSSION

We compared variability in connectivity strength within the DMN between medication-free individuals with major depression and matched healthy controls. We found that connectivity between the mPFC and PCC, two key nodes in the DMN, was significantly more variable in currently symptomatic patients with major depression. Furthermore, the validity of the results was confirmed in an independent sample of individuals with significantly more clinical heterogeneity, and using multi-echo acquisition parameters to limit the impact of non-neural signals. We believe this is the first time that greater connectivity variability has been reported in major depression in this DMN subsystem, complementing findings of reported abnormal dynamic connectivity in other brain regions in major depression[13] and other psychiatric conditions.[11,29,30]

In agreement with Kaiser *et al*.,[13] we demonstrated that the increased variability in neural connectivity originating from the mPFC correlates with a ruminative thinking pattern, indicating a possible synergy of this DMN subsystem with the 'salience network' represented by the insula.[14] This previous study, a whole-brain analysis, demonstrated altered connectivity variability between the mPFC and other DMN regions, but not specifically the PCC,[13] and variability in connectivity between the mPFC and parahippocampal gyrus was reduced. This might be explained by the more limited power in whole-brain analyses due to the necessary correction for multiple comparisons. Another possible explanation is that depression is associated with increased connectivity variability in the central DMN (including the PCC), while variability in the ventral system (including the parahippocampal gyrus) is reduced.

At present, the biological significance of time varying properties of connectivity is not well understood.[12] One potential explanation for the observed greater connectivity variability is that it results from reduced structural connectivity in the DMN as suggested by previous research linking structural integrity with connectivity variability.[31] However, our recent meta-analysis reported that structural integrity is maintained in the tracts connecting these regions in major depression,[7] suggesting that such an explanation is unlikely, further supported by our finding of no alteration in grey matter volume in the ROIs in these patient samples. It is also possible that greater connectivity variability reflects primary alterations in neuronal communication rather than occurring secondary to aberrant structural connectivity, a suggestion that is in line with preclinical work showing primary abnormalities of neural processing in circuits relevant to depression.[32] Clarifying the precise meaning of connectivity variability, and how it relates to connectivity strength, at a neural level will be an important task for future research.

We also tested the hypothesis that a ruminative cognitive style, linked with depression,[8,33] potentially explains the observed abnormalities in connectivity variability between mPFC and PCC. We observed a direct positive correlation between levels of intrusive, self-generated, ruminative thoughts and variability in connectivity within this network. This was, however, present only in the validation sample. This discrepancy in the results can be explained by issues related to statistical power combined with variability in the samples clinical characteristics. Patients in the validation sample were in fact characterized by higher rumination scores and comorbid anxiety disorders. It is possible that this result is reflective of a stronger link between anxiety symptoms and rumination,[34] and further work could clarify this. The difference between samples may also be related to differences in image acquisition and preprocessing. It is also possible that connectivity variability might be more closely linked to 'state' rumination levels occurring at the time of scanning rather than more ingrained 'trait' measures such as the RRS or to state anxiety, which we did not assess here. This is supported by work adopting post-scan cognitive style reports in healthy volunteers.[35] This study suggested a positive correlation between variability in the DMN and reported daydreaming (a related phenomenon to rumination) during MRI scanning, consistent with our findings.

We found no association in either sample between variability and depression severity scores. This may suggest that increased variability is not directly related to depressive symptoms. However, it is possible that this could be due to the Montgomery–Åsberg Depression Rating Scale, our measure of symptom severity, being weighted towards somatic rather than cognitive symptoms of depression. Previous research suggests that alterations in DMN connectivity are more likely to be related to psychological symptoms such as negative self-related cognitions.[33] Another possible explanation is that the relationship between biological disease mechanisms and symptoms is complex, and tend not to correlate linearly with one another.[11]

We found no alterations in static connectivity strength in both our samples in agreement with some studies[36] but not others.[37] Discrepancies in the findings can be explained by methodological differences in connectivity measurements, the proneness of neuroimaging data to type I/II error based on their relatively moderate sample sizes as indicated by recent meta-analyses[4] and multiple sources of heterogeneity intrinsic to major depressive disorders. We adopted a cross-validation method applied for the first time to this type of data to help enhance robustness of the findings. Based on our experience, future studies could consider a similar approach with larger samples, perhaps in the context of collaborative mega-analyses[38] to reduce statistical bias and increase power.

In addition to this potential link between connectivity instability and alterations in cognitive or emotional state, such as rumination, instability may also reflect increased noise or alterations in neural dynamics. Simulation studies have indicated that patterns of synchronization and desynchronization in neuronal populations lead to fluctuations in functional connectivity as measured using fMRI,[39] while noise-driven neuronal simulations produce switches between states of functional connectivity.[40] Notably, simultaneous electroencephalography and fMRI have shown that changes in the BOLD functional connectivity mirror electroencephalography power fluctuations[41] further indicating that variations in the functional connectivity are reflective of neuronal processes. It is possible that fluctuations in connectivity may reflect underlying changes in neural synchrony, a key process in inter-regional communication, which has been proposed to be affected in a range of psychiatric disorders.[42]

It has previously been suggested that hyperconnectivity implies lower variability in connectivity.[13,43] However, this is at odds with our results as we did not find group differences in static connectivity. Hence, the relationship between dynamic and static connectivity appears complex, with dynamic functional connectivity providing distinct information about network communication in a state of pathology independent from and beyond that of static connectivity. This echoes findings from previous research that attempted to classify patients with schizophrenia, bipolar disorder and healthy controls based on functional connectivity, indicating that classification using a combination of static and dynamic connectivity tends to be more accurate than static connectivity alone.[11,44]

A notable strength of this study is the control of non-neural influences on the data. The resting-state fMRI analyses are susceptible to influence from confounding factors such as motion and physiological variables,[24] and this is especially pertinent here in view of the possibility that physiological characteristics such as heart rate may differ between groups due to increased anxiety in patient groups. Consequently, we rigorously controlled for these in a number of ways, including correction for cardiac and respiratory signals, and motion scrubbing.[24] In our replication sample we used multi-echo fMRI with independent component analysis-based de-noising, which is more effective than traditional de-noising methods,[15] providing further evidence that our original results were not a result of non-neural influences. Moreover, our negative control analyses indicate that our findings were specific to the disease-relevant network under investigation, and groups did not differ on motion parameters.

Further strengths of the present study are the inclusion of medication-free patients, suggesting that the findings are not due to pharmacological effects. In addition, many patients in the primary sample were medication-naive and had experienced few, if any, past depressive episodes, making it less likely that the effects observed are cumulative effects of illness or previous treatment. The demonstration of greater connectivity variability in the validation sample, which included patients with more chronic and heterogeneous illness and used multi-echo fMRI, increases confidence in the reliability of the findings, which are unlikely to be attributable to idiosyncrasies of a specific sample or methodological artefacts. This is particularly important in view of concerns regarding poor reproducibility in research.[45] Replication is an important step towards minimizing false associations and enhancing reliability of results,[45] and the reproducibility demonstrated here suggests that alterations in dynamic functional connectivity are robust. Future replications of these results are warranted, and it would be of particular interest to examine connectivity variability in non-symptomatic individuals with depression and 'at risk' samples to test whether it is a feature of the depressive state, a marker of vulnerability to depression or a 'scar' effect.

One limitation of this study is the focus on two isolated regions of the DMN. We chose these regions given their key role in the DMN, and association with rumination in major depression.[8,9] Focusing on *a priori* regions of interest nevertheless increased the power to detect changes given the relatively small sample sizes. Additional analyses to confirm the replicability of previous findings, such as altered dynamic connectivity with the insula, would have been of interest; however, we chose to focus on one particular component of the DMN to reduce the likelihood of type II errors due correction for multiple comparisons with a small sample.

Furthermore, alternative methods to sliding window analyses, such as coherence-based methods, have been proposed that may provide more accurate estimations of dynamic functional connectivity.[12] Given their novelty, we have however chosen to use a more established method that has been evaluated in numerous studies. It is also possible that using different window lengths may affect the analysis. We believe the 40 s windows used here is an optimal length for detecting alterations in dynamic functional connectivity (see Supplementary Material for further discussion of this issue). In addition, our imaging sequences were only 6 and 8 min long for the primary and replication sample respectively. This may have limited our ability to detect less-frequent fluctuations in connectivity. Furthermore, our replication data and analysis differed slightly from our primary sample in acquisition and de-noising methods, making this more of a conceptual than methodological replication. Nevertheless, the fact that our results were largely consistent despite these dissimilarities suggests that the effect is robust.

In view of the presence of a range of anxiety disorders in the validation sample, it is not possible to determine whether altered connectivity variability might be a common abnormality present in both major depression and anxiety disorders rather than being specifically associated with depression. High comorbidity rates between anxiety and depressive disorders and the co-occurrence of anxiety symptoms in major depression are frequent findings in clinical practice.[1] This makes the differentiation challenging to establish. Lastly, it should be noted that the sample sizes used here were relatively small. Nonetheless, the consistency of our results across two independent samples indicates that our results are unlikely to be spurious.

In conclusion, our study indicates that major depression is associated with reduced stability of connectivity within the DMN in key regions relevant to the generation of ruminative cognitions. This could represent an intrinsic neural property of this illness and a potential network-specific brain abnormality not previously explained by structural abnormalities or static functional connectivity. The results were replicated in a second independent sample, indicating that they are robust. Ruminative cognitive style might partially explain the results in keeping with cognitive models of depressive disorders. This work adds to functional connectivity research in affective disorders by validating new findings across different samples with novel fMRI analysis techniques. Further work investigating trait markers of vulnerability to depression and connectivity variability in remitted patients are necessary to establish the specificity of these findings to the depressed state. Similarly, longitudinal studies are required to explore the effect of treatment on these abnormalities.

CONFLICT OF INTEREST

AJC has in the last 3 years received honoraria for speaking from AstraZeneca, honoraria for consulting from Allergan and Livanova and research grant support from Lundbeck. DJL has consulted for Ixico PLC. AHY has given paid lectures and sits on advisory boards for all major pharmaceutical companies with drugs used in affective and related disorders; is the lead investigator for the Embolden Study (AZ), BCI Neuroplasticity study and Aripiprazole Mania Study and investigator-initiated studies from AstraZeneca, Eli Lilly, Lundbeck and Wyeth; and has received grant funding from the National Institute of Mental Health (USA); Canadian Institutes of Health Research (Canada); National Alliance for Research on Schizophrenia and Depression (USA); Stanley Medical Research Institute (USA); Medical Research Council (UK); Wellcome Trust (UK); Royal College of Physicians (Edinburgh); British Medical Association (UK); University of British Columbia-Vancouver General Hospital Foundation (Canada); Western Economic Diversification Canada (Canada); Canadian Cardiovascular Society Depression Research Fund (Canada); Michael Smith Foundation for Health Research (Canada); and National Institute for Health Research (UK). AMP is supported by Bionomics Limited. DA has received travel grants from Janssen-Cilag and Servier. SCRW has received grant funding from the Medical Research Council (UK); Wellcome Trust (UK); National Institute for Health Research (UK) and support for investigator-led studies from Takeda, Pfizer, Lundbeck, P1Vital, Roche and Eli Lilly. The remaining authors declare no conflict of interest.

ACKNOWLEDGMENTS

The primary study was funded by Academy of Medical Sciences grant AMS-SGCL8 to DA and a National Institute of Health Research (NIHR) PhD studentship to TW supervised by AJC and DA. The validation study was funded by a Medical Research Council (MRC)/IoPPN Excellence PhD studentship to LM, supervised by AJC and AMP, and departmental funds generated by AJC and SCRW. AJC, AMP, SCRW, TW and AHY are supported by the NIHR Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London. This study represents independent research part funded by the NIHR/Wellcome Trust, King's College Hospital Clinical Research Facility and the NIHR Biomedical Research Centre at South London and Maudsley NHS Foundation Trust and King's College London. AH-V was supported by a Chilean Bicentennial Fund Scholarship from the Bicentennial Fund for Human Capital Development (Becas Chile) and by the Psychiatric Research Trust. We thank the staff of the NIHR/Wellcome Trust Clinical Research Facility at King's College Hospital, the Centre for Neuroimaging Science at King's College London and Dean Broadhurst, and Michael Kelly of the MHRN for their support in the conduct of the study. We thank all the participants of this study for their support.

Intermittent Stimulation of the Nucleus Basalis of Meynert Improves Working Memory in Adult Monkeys

Highlights

- Intermittent stimulation of nucleus basalis (NB) improves working memory performance
- Continuous NB stimulation degrades performance in young adult monkeys
- Donepezil provided no greater improvement than intermittent stimulation
- Effects were blocked by nicotinic and muscarinic receptor antagonists

In Brief

Liu et al. show that an intermittent train of electrical stimulation in the nucleus basalis improves working memory in adult monkeys. The improvement depends on cholinergic receptors. The finding reveals a new mechanism to improve cognitive performance in conditions that compromise cholinergic action, including aging and Alzheimer's disease.

SUMMARY

Acetylcholine in the neocortex is critical for executive function [1–3]. Degeneration of cholinergic neurons in aging and Alzheimer's dementia is commonly treated with cholinesterase inhibitors [4–7]; however, these are modestly effective and are associated with side effects that preclude effective dosing in many patients [8]. Electrical activation of the nucleus basalis (NB) of Meynert, the source of neocortical acetylcholine [9, 10], provides a potential method of improving cholinergic activation [11, 12]. Here we tested whether NB stimulation would improve performance of a working memory task in a nonhuman primate model. Unexpectedly, intermittent stimulation proved to be most beneficial (60 pulses per second, for 20 s every minute), whereas continuous stimulation often impaired performance. Pharmacological experiments confirmed that the effects depended on cholinergic activation. Donepezil, a cholinesterase inhibitor, restored performance in animals impaired by continuous stimulation but did not improve performance further during intermittent stimulation. Intermittent stimulation was rendered ineffective by either nicotinic or muscarinic receptor antagonists. In the months after stimulation began, performance also improved in sessions without stimulation. Our results reveal that intermittent NB stimulation can improve working memory, a finding that has implications for restoring cognitive function in aging and Alzheimer's dementia.

RESULTS AND DISCUSSION

Five adult Rhesus monkeys were trained with a delayed match-to-sample task, requiring them to remember a stimulus presented on a touch screen and, after a delay period, to select the stimulus that was initially presented (Figure 1). Once the animals were proficient with the task, they were implanted bilaterally with NB stimulation electrodes. Placement and anatomical verification are described in STAR Methods. The zone of stimulation was broad, on the order of a 4-mm-diameter sphere [15], and the accuracy of placement of the electrode tip within the nucleus was not critical in this experiment. Experiments in the first two animals (K and S) primarily guided proper positioning of stimulation leads in the next three (CH, DI, and PU). No histological confirmation of electrode placement occurred in these three animals, and electrode positioning is presumptive based on stereotaxic targeting.

Effects of Electrical Stimulation Parameters

We initially tested the hypothesis that NB stimulation improves working memory performance by applying a continuous train of stimulation pulses in blocks of 100 trials interleaved with blocks of 100 trials without stimulation. Contrary to our expectations, we found that continuous stimulation always impaired performance, and effects were larger at higher stimulation rates (Figure 2A). Results for continuous stimulation at 80 Hz reached statistical significance (binomial tests; animal CH: $n = 800$ trials, $p < 0.0001$; animal DI: $n = 1000$, $p < 0.001$).

In an effort to determine whether stimulation during a particular interval of the task was disrupting working memory, the task was altered to stimulate only during the inter-trial period or to stimulate only during trials. Unexpectedly, either condition resulted in supranormal performance. We established an intermittent stimulation condition that provided 20 s of pulses at a rate of 60 per second followed by 40 s without pulses. Results from this condition are shown in Figure 2B. Trials with stimulation resulted in better performance than trials with no stimulation in the animals tested (binomial test, $n = 1000$, $p < 0.01$). Note that a longer delay period was used in Figure 2B than in Figure 2A to avoid ceiling effects. We conclude that intermittent stimulation results in supranormal working memory performance.

We explored the parameters for optimal stimulation in two ways. First, the number of pulses per minute was fixed, and the duration and rate of stimulation were altered. The 1,200 pulses per minute were delivered in 10 s (i.e., at a rate of

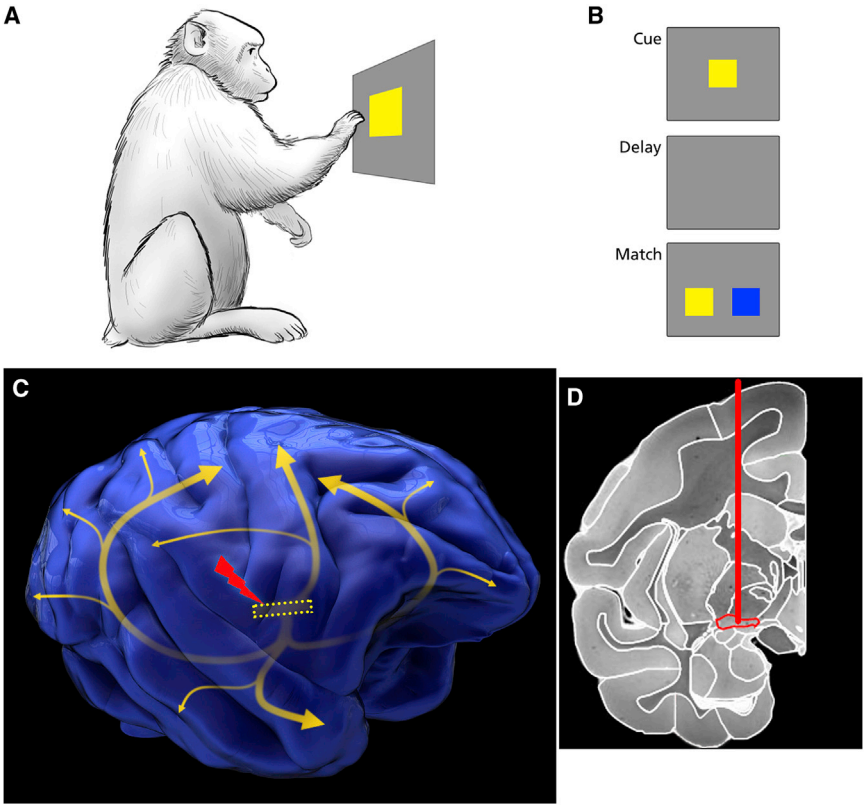

Figure 1. Task Paradigm and Electrical Stimulation Position in the Brain

(A) Macaque monkeys were trained to interact with a touchscreen. The first step in the task is touching the cue.

(B) After the cue is touched, the screen blanks during the delay period, followed by presentation of two potential matches. Three colors were used in training, and two were randomly selected as cue/match and distractor on each trial.

(C) Stimulation of the nucleus basalis (NB) of Meynert was used in experimental sessions. The position of the nucleus is shown by the dotted yellow rectangle, with the curved arrows approximating the pathways from the nucleus to neocortices [13].

(D) An MRI coronal section of a Rhesus monkey brain with the implantation target outlined in red. The MRI was taken from the Macaque Scalable Brain Atlas [14] (M.F. Dubach, and D.M. Bowden, 2009, Soc. Neurosci., abstract).

See also Figures S1 and S2.

120 Hz), 20 s, 40 s, or 60 s. Results are shown in Figure 2C for animals CH and DI. A two-way ANOVA found a significant effect of these conditions on performance (test for animal number and condition, $F(4,4) = 12.92$ for main effect of condition, $p < 0.02$; $F(1,4) = 1.48$ for main effect of animal, $p > 0.2$). Post hoc comparisons showed that performance was significantly better at the 10 or 20 s period than the 60 s condition of continuous stimulation (binomial statistic, ~1,050 trials for each condition, Bonferroni-corrected $p < 0.005$).

In a second experiment, the rate of stimulation was fixed at 80 pulses per second but the duration was varied to 10 s, 20 s, 40 s, or 60 s per minute (Figure 2D). A two-way ANOVA found a significant effect of condition and animal ($F(1,4) = 15.09$ for animal, $p < 0.02$; $F(4,4) = 8.48$ for condition, $p < 0.04$). The highest performance occurred for the 20 s stimulation condition, which was significantly better than the 60 s stimulation in post hoc tests (binomial statistic, ~1,350 trials each, Bonferroni-corrected $p < 0.005$). The significant ANOVA finding on the animal variable occurred as animal CH averaged higher performance in the 80 Hz stimulation conditions than animal DI. These parametric tests revealed that the condition of 1,200 pulses being delivered 15–20 s per minute was optimal within the parameters tested.

The effect of intermittent stimulation across varying delay periods can be seen in Figures 2E and 2F. The performance change, expressed as change in percent correct, was larger for longer delays, up to 5% improvement, than for shorter delays. However, the variability of the measure is a function of the percent correct, and if the percent correct is closer to 100, the variance is lower. To enable a fair comparison of the performance change caused by stimulation as a function of delay length, we converted these percent change differences to changes in signal size using the signal detection theory metric d' (see STAR Methods), which measured how far above the noise the signal size, or memory, rose. This metric inferred the signal size from the behavioral responses, and it was normalized by the noise standard deviation. Using either signal detectability metrics or percent correct, no statistically significant changes in stimulation effect were found as a function of delay length using ANOVAs ($p > 0.1$). Stimulation improved performance across the entire working memory delay curve, and the change in d' ranged from 0.13 to 0.39, with an average at the longest delay of 0.16. Alternately, if the animals were at zero delay and 96% correct, improvements were 1.4%–1.7%, while at longer delays animals improved 3.6%–4% above 75%. Changes of this magnitude reached statistical significance in two to four behavioral sessions.

Insight into the speed with which these effects occurred after stimulation began was determined by analyzing the performance shortly after a condition change. If effects appeared slowly, then performance shortly after stimulation began should be lower than performance later in the trial block. Similarly, if the effects decreased slowly once stimulation stopped, the no-stimulation blocks should have had lower performance later in the block. Performance compared to trial position in the block is shown in Figures S3A and S3B for continuous and intermittent stimulation. No significant trends based on position within the blocks were found, which indicated that effects occurred in less than 3 min, which was the average time to complete ten trials.

The Interactions of Stimulation Effects with Cholinergic Pharmacology

To test the hypothesis that the improvement of working memory performance after intermittent stimulation depended

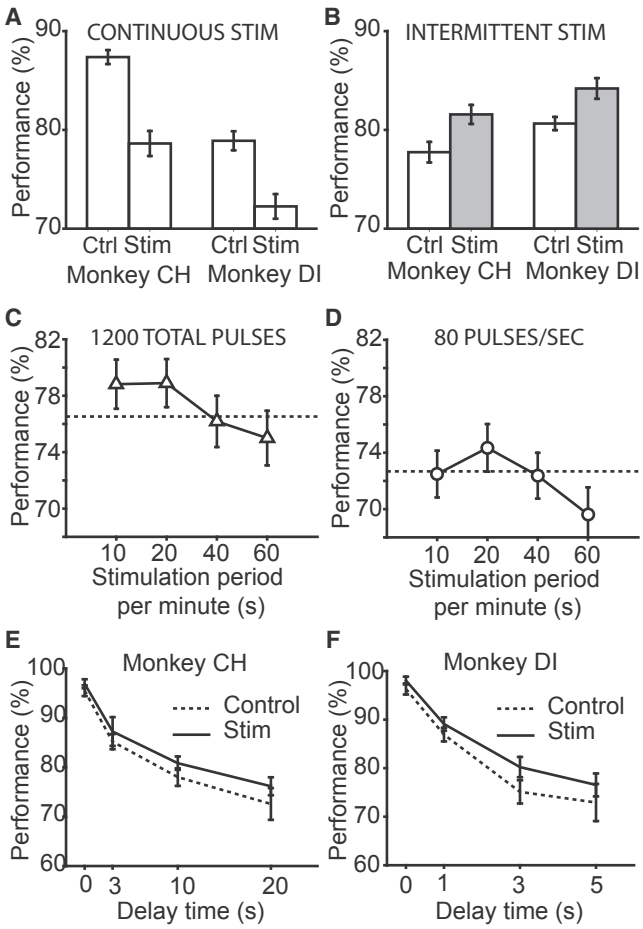

Figure 2. Effects of NB Stimulation on Working Memory Behavior

(A) The impact of continuous stimulation on performance. Monkeys performed the task with concurrent 80 Hz continuous stimulation or under a control condition.

(B) The impact of intermittent stimulation on performance. The gray bars indicate an intermittent stimulation condition distinct from the continuous stimulation condition indicated by empty bars in (A).

(C) Both monkeys were tested with 1,200 stimulation pulses per minute, delivered in 10 s (120 Hz), 20 s (60 Hz), 40 s (30 Hz), or 60 s (20 Hz). The performance under the control (no stimulation) condition for this week is indicated with the dashed line, and its standard error is 1.8%.

(D) Performance as both monkeys were tested with 80 pulses per second for different fractions of a minute. The standard error in control condition is 1.7%.

(E) Delay performance curve with and without intermittent stimulation in animal CH.

(F) Delay performance curve with and without intermittent stimulation in animal DI. Up to 1,000 trials were used to determine each point.

Error bars indicate the standard error of the mean. See also Figures S3 and S4.

on cholinergic pathways, stimulation was delivered with and without the cholinesterase inhibitor Donepezil. When the Donepezil dose was combined with intermittent stimulation, performance was no different from Donepezil alone, or stimulation alone, as shown in Figure 3A. The impact of combining Donepezil with 80 pulses per second continuous stimulation is shown on the right in Figure 3A. Continuous stimulation significantly impaired performance, but Donepezil reversed this impairment and resulted in supranormal performance. In Figure 3A, all comparisons relative to the control condition were significant (binomial test, $n > 3{,}000$ for each condition, $p < 0.005$ each). The result suggested that intermittent stimulation achieved a ceiling effect on cholinergic pathways. It also suggested that continuous stimulation degraded behavior by decreasing acetylcholine levels.

A further test of the cholinergic basis of effects was conducted using acetylcholine receptor antagonists. Mecamylamine was used to block nicotinic acetylcholine receptors in one set of experiments, and scopolamine was used to block muscarinic acetylcholine receptors in the second set of experiments. In either case (Figure 3B), intermittent stimulation did not improve performance ($p > 0.1$). The result suggested that both receptor subtypes were necessary for the performance increase caused by intermittent stimulation. As shown in Figure 3C, administration of mecamylamine and scopolamine alone reproduced known effects [16, 17]. Scopolamine impaired working memory (binomial test, $n = 550$, $p < 0.001$). Mecamylamine, at the dose tested, improved working memory (binomial test, $n = 2{,}700$, $p < 0.001$).

Donepezil is reported to cause side effects including nausea, which limits its clinical efficacy in some patients [8, 18, 19]. We plotted food consumption of the animals under control conditions, days in which intermittent stimulation was delivered in blocks, and days in which Donepezil was given. The results (Figure 3D) showed a significant effect of condition (unbalanced ANOVA; $F(2,56) = 3.4$ for condition, $p = 0.04$; $F(1,56) = 1.85$ for animal, $p = 0.179$). Post hoc testing found that monkeys consumed less food on days in which Donepezil was given relative to days in which stimulation was given (t test, $t = 2.81$, $df = 35$, $p < 0.009$).

The reaction times of animals CH and DI to the cue and match are shown in Figure S4. These reaction times were measured in the same data shown in Figures 2E and 2F. Under no conditions were there significant effects of stimulation on reaction times (paired t tests, $p > 0.1$ for all), which argued against stimulation causing a general effect on arousal or alertness.

Prior work stimulating NB in anesthetized animals has demonstrated consistent spectrum shifts of cortical electroencephalogram (EEG) recordings [20–23]. The low-frequency portions of the EEG, under 12 Hz, tend to decrease in energy, or desynchronize, while the higher-frequency gamma range increases under some experimental conditions. We recorded the subcortical local field potential (LFP), via the stimulating electrode, immediately before and after stimulation during periods of intermittent and continuous stimulation in the awake animal. As shown in Figures S2A–S2D, consistent reductions in LFP power spectrum occurred as a result of intermittent stimulation. Similar effects occurred after continuous stimulation at 80 Hz, shown in Figures S2E and S2F. All effects were significant (t tests, $p < 0.001$, frequency bands <4 Hz, 4–8 Hz, 8–12 Hz, 12–20 Hz, 20–40 Hz).

Long-Term Changes Caused by Stimulation

Unexpected improvements in working memory performance were observed in the three animals that were tested with stimulation of NB for months. In each animal, the delay interval was adjusted to maintain performance between 75% and 80%. The first indication of this change is shown in Figure 4A, in animal CH. The working memory delay duration had been increased

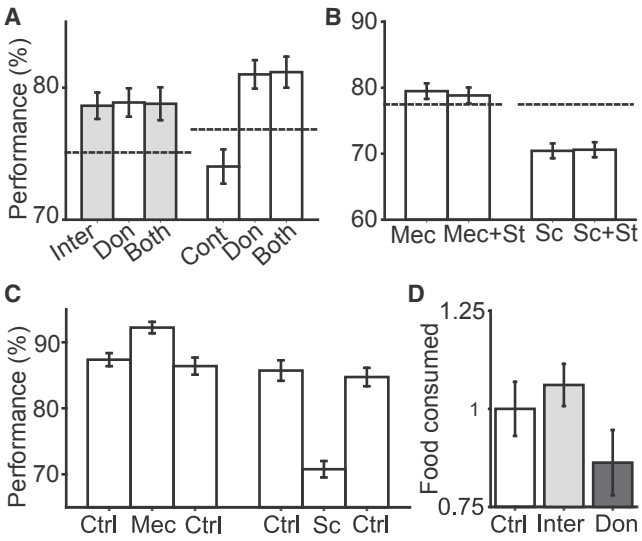

Figure 3. Pharmacological Interactions with Stimulation, and Effects on the Animals' Appetites

(A) On the left, the experimental conditions of intermittent stimulation (Inter) are compared to control (dashed line), Donepezil (Don), and both stimulation and Donepezil (Both). On the right, in a separate experiment, the same comparisons are applied with continuous stimulation (Cont). The gray bars indicate intermittent stimulation involved. Standard errors for control conditions (dashed lines) on the left and right are 1% and 1.1%, respectively.

(B) Effects of stimulation and acetylcholine receptor blockers. Mecamylamine (Mec) was given to animals prior to behavior, and working memory performance was assessed during intermittent stimulation and without stimulation. Scopolamine (Sc) was similarly tested. Average of the two animals tested in each condition is displayed. Dashed line shows the baseline performance in control condition, and standard error is 1.6%.

(C) Effects of Mecamylamine and Scopolamine. Animals performed behavior in control condition (left Ctrl), then were given Mecamylamine (Mec), or Scopolamine (Sc). Then animals performed washout behavior (right Ctrl, 72 hr after drug application).

(D) Effects of stimulation and Donepezil on appetite. Individual animal consumption under all conditions was normalized by mean control consumption to allow pooling across animals for this plot. Food consumption data were collected from animals CH and DI.

Error bars indicate the standard error of the mean.

from 6 s to 30 s over 9 weeks. Animal CH was improving shortly before stimulation was introduced, so further improvement could have been caused by a long-term stimulation effect or a continuation of an improvement trend.

Figures 2E and 2F give a chance to convert stimulation effects into equivalent changes in delay length. If the working memory delay chosen caused an animal to perform close to 75% correct, and the delay were halved, performance would have increased 5%–6%. This increase is slightly larger than the impact of intermittent stimulation shown in Figure 2B. A 5-fold decrease in the length of the delay period corresponds to a 12%–14% increase in percent correct. In signal-detection terms, a 14% increase in performance, from 75% to 89%, corresponds to a d' change of 0.78, which is 4.9 times greater than the average acute d' change caused by stimulation at long delays in Figures 2E and 2F.

Animal DI was allowed to reach asymptotic performance in the absence of stimulation for a longer period, and performance was stable over 11 weeks with a working memory delay of 2–3 s. Over the ensuing 5 months, the working memory delay increased from 3 s to 10 s, which is shown in Figure 4B. Under the null hypothesis that working memory ability was stable, this change was highly significant (binomial model, see STAR Methods, $p < 10^{-5}$). Animal PU (Figure 4C) performed the task for 17 weeks prior to initiating stimulation. Its performance was stable in this pre-stimulation period. In the following 7 weeks, the 1.5 s delay increased to 8 s, more than 5-fold, which again was significant ($p < 10^{-5}$). The results from animals DI and PU showed that stimulation increased working memory duration. All of the performance data used in this analysis were collected under control conditions, i.e., without the acute boost in performance shown in Figure 2B. For all data shown in Figure 4, the stimulation delivered in the several-month-long period of stimulation was mixed while the experiments of Figures 2, 3, and 4 were conducted.

DISCUSSION

The delayed match-to-sample task was used because it is a well-studied test of executive function in the nonhuman primate [24]. It embodies several mnemonic processes that are critical to human cognition, including attention, stimulus discrimination, encoding, and memory for recent events [25]. The task is sensitive to cholinergic modulation, as indicated by its enhancement by cholinesterase inhibitors [26, 27], and to cholinergic receptor agonists [28, 29], and it is sensitive to impairments of performance by cholinergic antagonists [17, 30]. Intermittent stimulation of NB led to short-term improvement in the task, whereas continuous stimulation suppressed performance. Pharmacological administration of cholinesterase inhibitors and acetylcholine receptor blockers demonstrated that the effects occur through modulation of acetylcholine levels and require activation of both classes of acetylcholine receptors. Unlike cholinesterase inhibitors, appetite is not suppressed by cholinergic modulation through deep brain stimulation. Even though stimulation was delivered in varied amounts each week, each of three animals increased their working memory delay duration 3- to 5-fold in the months after stimulation began. Two of those animals had extended periods of stable task performance before stimulation began. Future work may address the specificity of these effects, because working memory only comprises one component of executive function.

A major unexpected finding in this study is the form of stimulation that produced optimal results: 60 pulses per second delivered for 20 s and followed by 40 s without stimulation. Deep brain stimulation's mechanisms have been a subject of debate [31]. Locally, a depolarization block and possibly activation of local inhibitory circuits dominates to prevent somatic activation, whereas recording and imaging evidence suggests that axonal efferent outflow is activated by each stimulation pulse. Accordingly, the NB axons should be activated each time a pulse is delivered. Why the intermittent pattern results in more cortical acetylcholine, as inferred from pharmacological experiments, than continuous stimulation is an obvious question for subsequent studies. We speculate that intermittent, not continuous, neuronal stimulation results in higher levels of acetylcholine synthesis and release. The rate-limiting step in acetylcholine synthesis is the uptake of choline from the synaptic cleft via the high-affinity choline transporter hCHT [32]. Before release,

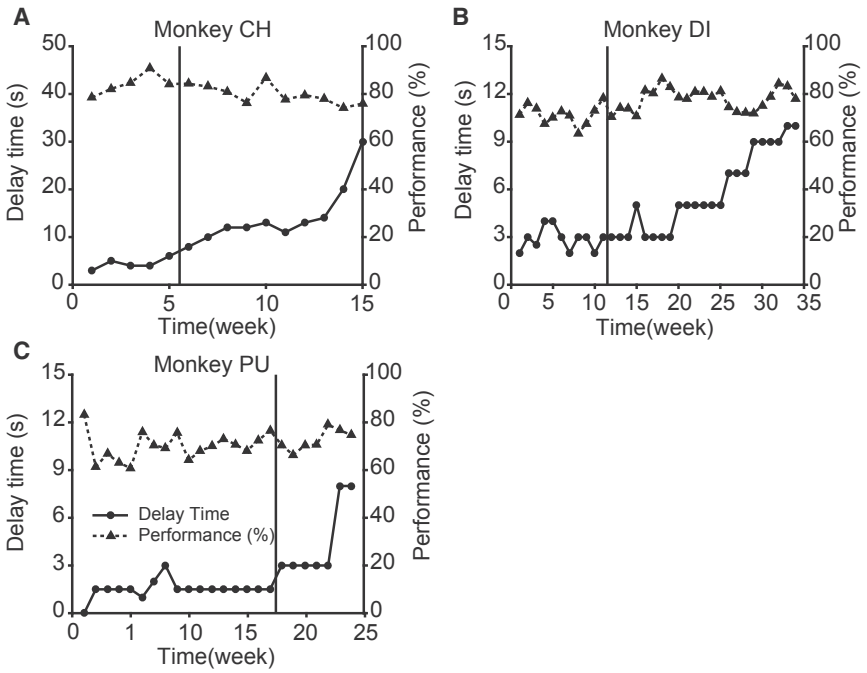

Figure 4. Changes in Working Memory over Time

(A) The working memory delay and performance for animal CH. Delay and performance are plotted against time relative to initiating intermittent stimulation. The delay was chosen to maintain performance range. The vertical line before week 6 indicates when intermittent stimulation was introduced. Left axis illustrates the delay, which is marked by circle symbols, while the right axis illustrates the performance, plotted as triangles. All data in this figure are defined under no-stimulation control conditions.

(B) Data for animal DI.

(C) Data for animal PU.

the proton-exchanging acetylcholine transporter VAChT brings more acetylcholine into the vesicle, and the high-affinity choline transporter, which would transport choline to the cytosol, is turned off by the low vesicular pH [33, 34]. After release, the vesicular membrane becomes part of the cell membrane, and the decreased proton concentrations turn the acetylcholine transporter off and the choline transporter on. If frequent vesicular release from high-frequency stimulation alters post-release activation of the high-affinity choline transporter by changing local pH, overall acetylcholine synthesis and release could be reduced.

A similar curiosity is that the stimulation does not have any temporal relation to the behavioral task or to known cholinergic kinetics other than the recycle time [35, 36]. Donepezil's effects on behavioral performance are arguably boosting the efficacy after normal cholinergic release, which would preserve the normal temporal function of acetylcholine [26]. However, some experiments with subtype-selective agonists also improve working memory function [37–39], and these would similarly lack any temporal specificity.

Improvement in cognition from cholinergic system activation could be caused by cholinergic modulation of neurons or by cholinergic-induced increases in blood flow, and these mechanisms are not mutually exclusive. In the neocortex, cholinergic activation of neurons leads to increased thalamic input into layer IV while suppressing other cortical inputs [40, 41]. This, at least partly, explains how the activation of the cholinergic system desynchronizes the EEG and local field potential (Figure S2), which was also reported by previous studies [21, 22, 42, 43]. The coupling of desynchronization to behavioral improvements suggests that direct cholinergic modulation of neurons improves the behavior.

At the same time, we cannot exclude the possibility that indirect mechanisms such as increases of blood flow played a role in the improved cognitive performance. In the brain, acetylcholine is acting on both neurons and glia adjacent to blood vessels [44, 45]. Cholinesterase inhibitors in humans cause an increase of 10%–15% in cerebral blood flow [46], and this blood flow is typically reduced in Alzheimer's patients [47–49]. Reductions in cerebral blood flow likely contribute to the cognitive impairments [50]. Future work may shed light on the relative contributions of neural modulation and blood flow regulation in these effects, as well as on the question of their independence.

The long-term effects observed indicate that working memory duration is increased 3- to 5-fold in each of three animals tested over periods of up to 5 months. The changes even occurred after long stable performance periods prior to stimulation. These results suggest that cholinergic modulation combined with executive function behavior causes brain plasticity to support behavioral improvements. Prior work has associated phasic stimulation of NB with neural plasticity in the sensory cortex [20, 22, 51].

Several clinical trials have been conducted on deep brain stimulation of cholinergic pathways [52, 53]. None have found consistent cognitive improvement using continuous stimulation. Similarly, animal work with continuous stimulation finds weak to no effects on learning and memory [11]. We measured analogous effects using continuous stimulation, which also suggest that high-frequency continuous stimulation suppresses acetylcholine levels. Our data show that making the stimulation intermittent is critical to turning cognitive suppression into cognitive enhancement. Animals had stronger appetites while receiving stimulation than while receiving Donepezil. The use of the intermittent stimulation parameters outlined in this work reach efficacies as high as those of high doses of cholinesterase inhibitors without peripheral side effects and point toward new candidates for therapeutic treatment of Alzheimer's dementia.

EXPERIMENTAL MODEL AND SUBJECT DETAILS

Animal Model

Five rhesus monkeys (*Macaca mulatta*) were used in this study. Two initial animals (K and S) were used to optimize the placing of the stimulation electrodes. These were a 7 years old male and a 12 years old female weighing 7 and 6 kg. The three subsequent animals (animals CH, DI, and PU), used for data in Figures 2–4, were male, 6 years old and weighed 8 −11 kg. The monkeys were pair-housed in 12-h light/dark cycle rooms. All monkeys were task naive at the start of the experiments. All animals were chaired during task performance, with one arm restrained to both establish consistency in the arm used to perform the task, and to prevent spinning in the primate chair. Animals were not head fixed during task performance.

All animal studies comply with the Guide for the Care and Use of Animals, 8th Edition, and were approved by the IACUC at Augusta University.

METHOD DETAILS

Behavioral Task

All behavioral software was based on prior work [28], and available from PBTLI Prime Behavior Testing Laboratories, Inc, http://www.pbtli.com/, Augusta, GA. The behavioral task, shown in Figure 1, initiated with a colored square cue in the center-top part of the touchscreen. After the animal touched the square, the cue disappeared, and the screen remained blank for the delay period. In the match phase, two colored squares were presented in the lower right, and lower left, of the touchscreen. One of the two squares, randomized in location, had the same color as the cue square. Correctly touching the target square resulted in delivery of food slurry reward, while incorrect responses resulted in doubling the inter trial period as a brief timeout. The animal reaction times were not strongly constrained. Animals had 10 s to make a response. Percent correct and reaction times were recorded. Animals required several months of daily training to achieve stable performance at the task. Three colors (red, blue and yellow) were used. In each trial, two were randomly chosen as cue/match, and as the distractor.

Dates of data collection for each animal for each figure.

Surgery and Deep Brain Stimulation

Surgery was performed in a sterile surgical suite under isoflurane anesthesia monitored by a clinical veterinarian. Stereotaxic measurements were made to target implantation. In our first two animals, targeting was 8mm lateral, 12 and 14 mm anterior interaural respectively, and 29 mm below the cortical surface in a vertical penetration. The final three animals were implanted at 16 mm anterior interaural with the same lateral and depth coordinates. The final lateral and anterior coordinates, and depth, were chosen to correspond to the center of the anterior portion of the Nucleus Basalis of Meynert, which would contain the highest density of projections to the prefrontal cortex [10, 54, 55]. At the targeted brain position, the stimulation region, which is estimated to be a 4 mm diameter sphere [31], should include the Nucleus Basalis of Meynert as well as portions of the anterior amygdala including the central nucleus, the anterior commissure, and the inferior internal globus pallidus [56]. A skin flap was performed, and two holes were drilled above the location of each implant. A small cylindrical titanium chamber (5-mm inner diameter and 7-mm outer) was mounted on the cranium and the skin was sutured into place leaving the chamber exposed. A 26 ga. hypodermic guide tube was lowered and the tip advanced 5 mm below the dura mater. The electrode was inserted into the guide tube, and a stylus was used to push it to the appropriate depth. The use of the guide tube and stylus followed published methods [57, 58], which are analogous to methods used in human neurosurgical deep brain electrode implantation. The guide tube was then raised while the stylus depth maintained. The chamber was evacuated of fluid, flushed with ceftriaxone, and thereafter fluid evacuated a second time. Silicone was poured into the chamber to seal the fenestrations in the skull and the inside of the chamber. The electrode was fixed in depth with a drop of cyanoacrylate, and its rear wire was stripped and soldered to a connector that was fixed on the chamber outer wall. One week after the surgery, the animals returned to behavioral studies.

The stimulation pulses were created by a multiple functional I/O device (USB-6211, National Instruments, Austin, TX), which was controlled by a custom programed software. Impedances of electrodes were checked daily prior to each behavioral session so that stimulation voltages could be tailored to deliver the appropriate currents (200 μA). Continuous stimulation was performed from 20 pulses per second to 120. Intermittent stimulation was initially applied at 60 pulses per second only in-between trials, or only during trials, which were roughly 3 and 5 s periods. Thereafter, experiments standardized on intermittent stimulation using a one-minute cycle length, and stimulation for 20 s at 60 pulses per second, followed by 40 s with no stimulation. In these one-minute cycle stimulation experiments, no attempt was made to synchronize the stimulation with the behavioral trials.

Electrodes were custom manufactured in our laboratory based on published specifications [57, 58]. Conductors were 50 μm Pt/Ir, Teflon-insulated wire (A-M systems, Seattle, WA) embedded within a 30 ga. hypodermic tube, which was encased in a 28 ga. polyimide sheath. The wire extended from the end of the sheath into the brain tissue by roughly 1 mm, and the last 0.7 mm of insulation was stripped to achieve impedances of 5-10 kOhm at 1 kHz. The far end of the electrode was soldered to an extracranial connector fixed on the chamber outer wall. Preliminary experiments on electrode placement in the two pilot animals tested the effects of short periods of stimulation on EEG desynchronization. Stimulation was delivered with biphasic, negative first, unipolar 200 μA pulses with 100 μS per phase, and 10 pulses were delivered in 100 msec. Under anesthesia, this resulted in EEG desynchronization when averaged over 10 trials when the electrode was at a depth corresponding to the atlas position of Nucleus Basalis. EEG was recorded with × 1000 gain from two bone screws at the same M-L position, with one near vertex, and one lateralized. An electrode movement vertically in either direction of more than 1 mm was adequate to make desynchronization not possible using the same protocol. After our second pilot animal, we determined the depth for our A-P and M-L coordinates was 29 mm below the cortical surface. We further recovered our electrode track from our second pilot animal, shown in Figure S1. It was implanted 2 mm more caudally than the electrodes from the three monkeys presented in the results. The tip of the electrode was centered 1 mm medial to Nucleus Basalis at 14 mm anterior interaural. After our pilot animals, we implanted to the same depth in all animals, and 2 mm more rostrally, for the current study, and measured LFP desynchronization in the awake animals using the stimulation electrode as the positive lead (Figure S2).

In these first two pilot animals, we frequently moved electrodes vertically to new positions. At this point in the study, we understood that the electrode depth at which EEG desynchronization occurred after brief phasic stimulation precisely matched that at which 80 Hz continuous stimulation resulted in significant performance decrements. The rear ends of the electrodes were always visible, protruding from the implanted titanium cylinder, which gave an absolute depth measurement.

Pharmacology and Stimulation Studies Administration

We used donepezil, mecamylamine and scopolamine (Sigma-Aldrich, St. Louis, MO) in this study. The drugs were dissolved in a 0.5 cc saline vehicle to an amount specified by the experiments (donepezil: 200 μg/kg, mecamylamine: 300 μg/kg and scopolamine:

6.2 μg/kg). Donepezil was given via I.M. administration 15 min before behavior testing on the mornings in which data was collected. The rationale for the doses selected for Donepezil was based on previous behavioral and functional brain imaging data (dose range 50-250 μg/kg) in rhesus monkeys [27, 59]. Data from days without donepezil were at least 72 hr after the last administration. Doses higher than 200 μg/kg could not be used in this study, as the animals administered these doses refused to engage in behavioral trials for food reward. Nausea is a well-known, clinical side effect of the drug in humans. Each week, control performance was evaluated. Then, performances under the intermittent stimulation alone, donepezil alone, and donepezil+stimulation were evaluated on successive days. Similar weekly plans were used for continuous stimulation, and mecamylamine (300 μg/kg) and scopolamine (6.2 μg/kg) testing. This weekly testing schedule was chosen over an intraday comparison because an intraday design would compare drug versus no-drug conditions at different times, and with different appetitive motivations. The recovery test sessions from drug were recorded 72 hr after drug application. The doses of mecamylamine and scopolamine used in this study refer to previous publications [16, 30].

Initial deep brain stimulation studies, shown in Figures 2A and 2B, provided stimulation in blocks. For continuous stimulation, 100 trials without stimulation were interleaved with 100 trials with stimulation. For intermittent stimulation, blocks were 50 trials. For Figures 2C and 2D, all stimulation conditions were executed randomly block by block and interleaved with each other. Each block also contained 50 trials. For Figures 3A–3C, we collected animals' performance data in control conditions for 1-2 days first, then collected performance data after administering pharmacological agents. Drug and Stim+Drug conditions were interleaved with each other in blocks of 50 trials. The recording procedures for the pharmacology experiments were 2-3 times to improve statistical power. For Figures 2E, 2F, and S4, which includes performance at different delays with and without stimulation, we tested the animals' performance with interleaved blocks in control and stimulation conditions. In each block, variable delay times were pseudo-randomly chosen and arranged in the test sequence. Software was administered directly from PBTLI software while a second computer was used to generate stimulation pulses. Data for Figure 4 were selected from all available data in which no drug or stimulation condition occurred.

Delay times used in each experiment.

QUANTIFICATION AND STATISTICAL ANALYSIS

d' Calculation

The signal detection theoretic d' is the salience of the target relative to the distractor as inferred from the animals' behavioral choices. In our two alternative forced choice framework, d' is calculated using only the percent correct with the MATLAB (Mathworks, Natick, MA) norminv function, as $\sqrt{2} * norminv(Hit\ Rate)$ [60, 61]. This metric measures the amount of the memory that is retained, on average. It assumes the memory can be measured in terms of a mean and a noise standard deviation. As time passes, that mean, or memory, regresses toward zero. The metric measures the magnitude, normalized by the noise standard deviation, of the mean at the end of the delay period. The following table details how d' relates to percent correct in the task.

d'	Percent Correct
0.25	57
0.5	64
0.75	70
1.0	76
1.25	81
1.5	85
1.75	89
2.0	92

Binomial Statistical Model

We relied on a binomial statistic model to test if Nucleus Basalis stimulation, over weeks and months, produced long-term improvements in working memory that could be measured which resulted in ability to perform the task at high performance with a longer delay interval (Figure 4). Prior to stimulation, animals performed 3000 trials weekly at a performance level averaging 78% correct, with a delay interval ranging between 1.5-6 s for the three animals. For each animal, we asked what performance improvement would occur if the delay, at which performance level is 78% correct, were doubled? In each animal's delay curves, shown in Figures 2E and 2F, halving the delay would result in changes in percent correct of 5.4 and 5.1 percent. In other words, if we time scaled the graphs in Figures 2E and 2F to the same percentage correct at twice the delays, animal performance at the original delay would be predicted, based on the delay curves in Figures 2E and 2F, to increase by just over 5%. We conservatively rounded this percentage to a 5 percent change. Next, the two-tailed probabilities were calculated that a binomial process with a fraction correct of 0.78 over 3000 trials could result in more correct trials than a process with a fraction correct 5 percent higher or lower. This probability is less than 10^{-5}. The implication of the binomial model is that if an animal performs at 78% correct for duration 2X, then it would be expected to perform at 83%, or higher, at duration X, and that this performance would be significantly better than its pre-stimulation performance of 78% at duration X.

Making health habitual:
the psychology of 'habit-formation' and general practice

MAKING HEALTH HABITUAL

The Secretary of State recently proposed that the NHS:

'... take every opportunity to prevent poor health and promote healthy living by making the most of healthcare professionals' contact with individual patients.'[1]

Patients trust health professionals as a source of advice on 'lifestyle' (that is, behaviour) change, and brief opportunistic advice can be effective.[2] However, many health professionals shy away from giving advice on modifying behaviour because they find traditional behaviour change strategies time-consuming to explain and difficult for the patient to implement.[2] Furthermore, even when patients successfully initiate the recommended changes, the gains are often transient[3] because few of the traditional behaviour change strategies have built-in mechanisms for maintenance.

Brief advice is usually based on advising patients on what to change and why (for example, reducing saturated fat intake to reduce the risk of heart attack). Psychologically, such advice is designed to engage conscious deliberative motivational processes, which Kahneman terms 'slow' or 'System 2' processes.[4] However, the effects are typically short-lived because motivation and attention wane. Brief advice on how to change, engaging automatic ('System 1') processes, may offer a valuable alternative with potential for long-term impact.

Opportunistic health behaviour advice must be easy for health professionals to give and easy for patients to implement to fit into routine health care. We propose that simple advice on how to make healthy actions into habits — externally-triggered automatic responses to frequently encountered contexts — offers a useful option in the behaviour change toolkit. Advice for creating habits is easy for clinicians to deliver and easy for patients to implement: repeat a chosen behaviour in the same context, until it becomes automatic and effortless.

HABIT FORMATION AND HEALTH

While often used as a synonym for frequent or customary behaviour in everyday parlance, within psychology, 'habits' are defined as actions that are triggered automatically in response to contextual cues that have been associated with their performance:[5,6] for example, automatically washing hands (action) after using the toilet (contextual cue), or putting on a seatbelt (action) after getting into the car (contextual cue). Decades of psychological research consistently show that mere repetition of a simple action in a consistent context leads, through associative learning, to the action being activated upon subsequent exposure to those contextual cues (that is, habitually).[7–9] Once initiation of the action is 'transferred' to external cues, dependence on conscious attention or motivational processes is reduced.[10] Therefore habits are likely to persist even after conscious motivation or interest dissipates.[11] Habits are also cognitively efficient, because the automation of common actions frees mental resources for other tasks.

A growing literature demonstrates the relevance of habit-formation principles to health.[12,13] Participants in one study repeated a self-chosen health-promoting behaviour (for example, eat fruit, go for a walk) in response to a single, once-daily cue in their own environment (such as, after breakfast). Daily ratings of the subjective automaticity of the behaviour (that is, habit strength) showed an asymptotic increase, with an initial acceleration that slowed to a plateau after an average of 66 days.[9] Missing the occasional opportunity to perform the behaviour did not seriously impair the habit formation process: automaticity gains soon resumed after one missed performance.[9] Automaticity strength peaked more quickly for simple actions (for example, drinking water) than for more elaborate routines (for example, doing 50 sit-ups).

Habit-formation advice, paired with a 'small changes' approach, has been tested as a behaviour change strategy.[14,15] In one study, volunteers wanting to lose weight were randomised to a habit-based intervention, based on a brief leaflet listing 10 simple diet and activity behaviours and encouraging context-dependent repetition, or a no-treatment waiting list control. After 8 weeks, the intervention group had lost 2 kg compared with 0.4 kg in the control group. At 32 weeks, completers in the intervention group had lost an average of 3.8 kg.[14] Qualitative interview data indicated that automaticity had developed: behaviours became 'second nature', 'worming their way into your brain' so that participants 'felt quite strange' if they did not do them.[10] Actions that were initially difficult to stick to became easier to maintain. A randomised controlled trial is underway to test the efficacy of this intervention where delivered in a primary care setting to a larger sample, over a 24-month follow-up period.[16] Nonetheless, these early results indicate that habit-forming processes transfer to the everyday environment, and suggest that habit-formation advice offers an innovative technique for promoting long-term behaviour change.[13]

MAKING HEALTHY HABITS

We suggest that professionals could consider providing habit-formation advice as a way to promote long-term behaviour change among patients. Habit-formation advice is ultimately simple — repeat an action consistently in the same context.[12] The habit formation attempt begins at the 'initiation phase', during which the new behaviour and the context in which it will be done are selected. Automaticity develops in the subsequent 'learning phase', during which the behaviour is repeated in the chosen context to strengthen the context-behaviour association (here a simple ticksheet for self-monitoring performance may help; Box 1). Habit-formation culminates in the 'stability phase', at which the habit has formed and its strength has plateaued, so that it persists over time with minimal effort or deliberation.

"Advice for creating habits is easy for clinicians to deliver and easy for patients to implement: repeat a chosen behaviour in the same context, until it becomes automatic and effortless."

"... typical [behaviour change] *advice ... emphasises variation in behaviours and settings ... . Variation may stave off boredom, but is effortful and ... incompatible with development of automaticity."*

Initiation requires the patient to be sufficiently motivated to begin a habit-formation attempt, but many patients would like to eat healthier diets or take more exercise, for example, if doing so were easy. Patients must choose an appropriate context in which to perform the action. The 'context' can be any cue, for example, an event ('when I get to work') or a time of day ('after breakfast'), that is sufficiently salient in daily life that it is encountered and detected frequently and consistently. A cue located within an existing daily routine (for example, 'when I go on my lunch break') provides a convenient and stable starting point.[10]

Keeping going during the learning phase is crucial. The idea of repeating a single specific action (for example, eating a banana) in a consistent context (with cereal at breakfast) is very different from typical advice given to people trying to take up new healthy behaviours, which often emphasises variation in behaviours and settings to maintain interest (trying different fruits with or between different meals). Variation may stave off boredom, but is effortful and depends on maintaining motivation, and is incompatible with development of automaticity.[6]

Patients should choose the target behaviour themselves. Progress towards a self-determined behavioural goal supports patients' sense of autonomy and sustains interest,[17] and there is evidence that a behaviour change selected on the basis of its personal value, rather than to satisfy external demands such as physicians' recommendations, is an easier habit target.[18] Patients need to select a new behaviour (for example, eat an apple) rather than give up an existing behaviour (do not eat fried snacks) because it is not possible to form a habit for not doing something. The automaticity of habit means that breaking existing habits requires different and altogether more effortful strategies than making new habits.[12]

Patients should be encouraged to aim for small and manageable behaviour changes, because failure can be discouraging. A sedentary person, for example, would be more appropriately advised to walk one or two stops more before getting on the bus than to walk the entire route — at least for their first habit goal. Small changes can benefit health: slight adjustments to dietary intake can aid long-term weight management,[19] and small amounts of light physical activity are more beneficial than none.[20] Moreover, simpler actions become habitual more quickly.[9] Additionally, behaviour change achievements, however small, can increase self-efficacy, which can in turn stimulate pursuit of further changes.[21] Forming one 'small' healthy habit may thereby increase self-confidence for working towards other health-promoting habits.

Unrealistic expectations of the duration of the habit formation process can lead the patient to give up during the learning phase. Some patients may have heard that habits take 21 days to form. This myth appears to have originated from anecdotal evidence of patients who had received plastic surgery treatment and typically adjusted psychologically to their new appearance within 21 days.[22] More relevant research found that automaticity plateaued on average around 66 days after the first daily performance,[9] although there was considerable variation across participants and behaviours. Therefore, it may be helpful to tell patients to expect habit formation (based on daily repetition) to take around

Box 1. A tool for patients

Make a new healthy habit

1. Decide on a goal that you would like to achieve for your health.
2. Choose a simple action that will get you towards your goal which you can do on a daily basis.
3. Plan when and where you will do your chosen action. Be consistent: choose a time and place that you encounter every day of the week.
4. Every time you encounter that time and place, do the action.
5. It will get easier with time, and within 10 weeks you should find you are doing it automatically without even having to think about it.
6. Congratulations, you've made a healthy habit!

My goal (e.g. 'to eat more fruit and vegetables') _____

My plan (e.g. 'after I have lunch at home I will have a piece of fruit')
(When and where) _____ I will _____

Some people find it helpful to keep a record while they are forming a new habit. This daily tick-sheet can be used until your new habit becomes automatic. You can rate how automatic it feels at the end of each week, to watch it getting easier.

	Week 1	Week 2	Week 3	Week 4	Week 5	Week 6	Week 7	Week 8	Week 9	Week 10
Monday										
Tuesday										
Wednesday										
Thursday										
Friday										
Saturday										
Sunday										
Done on >5 days, yes or no										
How automatic does it feel? Rate from 1 (not at all) to10 (completely)

E-mail: b.gardnersood@ucl.ac.uk

10 weeks. Our experience is that people are reassured to learn that doing the behaviour gets progressively easier; so they only have to maintain their motivation until the habit forms. Working effortfully on a new behaviour for 2–3 months may be an attractive offer if it has a chance of making the behaviour become 'second nature'.

CONCLUSION

Psychological theory and evidence around habit-formation generates recommendations for simple and sustainable behaviour change advice. We acknowledge that health professionals do not always find it appropriate to offer lifestyle counselling to patients: some patients can become annoyed when advised to change their behaviour, and this reaction can threaten patients' trust in and satisfaction with the doctor–patient relationship.[2] However, in settings where professionals feel able to offer behaviour advice, we suggest that they consider providing guidance on habit-formation. Habit-formation advice can be delivered briefly, it is simple for the patient to implement, and it has realistic potential for long-term impact. It offers health professionals a useful tool for incorporating evidence-based health promotion into encounters with patients. A sample tool for health professionals to use with patients to encourage habit formation is provided in Box 1.

Peer Influence on Risk Taking, Risk Preference, and Risky Decision Making in Adolescence and Adulthood: An Experimental Study

Margo Gardner and Laurence Steinberg
Temple University

In this study, 306 individuals in 3 age groups—adolescents (13–16), youths (18–22), and adults (24 and older)—completed 2 questionnaire measures assessing risk preference and risky decision making, and 1 behavioral task measuring risk taking. Participants in each age group were randomly assigned to complete the measures either alone or with 2 same-aged peers. Analyses indicated that (a) risk taking and risky decision making decreased with age; (b) participants took more risks, focused more on the benefits than the costs of risky behavior, and made riskier decisions when in peer groups than alone; and (c) peer effects on risk taking and risky decision making were stronger among adolescents and youths than adults. These findings support the idea that adolescents are more inclined toward risky behavior and risky decision making than are adults and that peer influence plays an important role in explaining risky behavior during adolescence.

Keywords: adolescents, risk taking, peer influence, risk preference, decision making

This document is copyrighted by the American Psychological Association or one of its allied publishers.
This article is intended solely for the personal use of the individual user and is not to be disseminated broadly.

It is well documented that adolescents are more likely than adults to engage in risky behavior. For example, adolescents are more likely than adults to drive recklessly, to drive while intoxicated, to use varied illicit substances, to have unprotected sex, and to engage in both minor and more serious antisocial behavior (Arnett, 1992). However, despite clinical and anecdotal evidence of heightened real-world risk taking during adolescence, laboratory studies of age differences in risk preference, risk perception, and risky decision making have not yielded consistent evidence that adolescents are actually less risk averse than are their elders. In fact, it is often asserted that, by midadolescence, teens' capacities for understanding and reasoning in risky decision-making situations roughly approximate those of adults (Fischhoff, 1992; Furby & Beyth-Marom, 1992). This assertion has been used to argue both for protecting adolescents' rights to make autonomous decisions about their reproductive health and for holding adolescents to adult standards of criminal blameworthiness (see Steinberg & Scott, 2003, for a discussion).

However, as several writers have recently argued, extant studies suggesting equivalent orientations toward risk among adolescents and adults are only modestly useful in understanding how adolescents compare with adults in real-world decision making. These authors suggest that typical laboratory studies of risky decision making fail to consider the emotional and social contexts in which risk taking actually occurs (Cauffman & Steinberg, 2000; Scott, Reppucci, & Woolard, 1995; Steinberg, 2004; Steinberg & Cauffman, 1996). In such studies, individual adolescents are presented with hypothetical dilemmas under conditions of low emotional arousal and are then asked to make and explain their decisions. In the real world, however, adolescents' decisions are not hypothetical, they are generally made under conditions of emotional arousal (whether negative or positive), and they are usually made in peer groups. Whether the risky decision making of adolescents is truly comparable to that of adults under real-world conditions remains an open and unstudied question.

A number of explanations have been advanced to account for differences between adolescents and adults in real-world, as opposed to laboratory-based, risk taking. Some have argued that age differences in psychosocial capacities such as impulse control or sensation seeking play an important role (see Steinberg & Cauffman, 1996). Consistent with this, Cauffman and Steinberg (2000) reported that once differences in psychosocial maturity between adolescents and adults are accounted for, age differences in risky decision making disappear. An alternative and entirely compatible account of age differences in risky behavior emphasizes the role of peers and, more specifically, peer influence. That is, adolescents may engage in more risky behavior than do adults because they are more susceptible to the influence of their similarly risk-prone peers. Support for this latter explanation comes, in part, from the criminology literature. There is a small but compelling body of evidence to suggest that when adolescents commit crimes—acts that are inherently risky—they generally do so with their peers (Erickson & Jensen, 1977; Zimring, 1998). For example, adolescents are usually accompanied by one or more persons when committing crimes that range in seriousness from vandalism and drug use (Erickson & Jensen, 1977) to rape and homicide (Zim-

ring, 1998). This is not, however, true of adults; when adults commit crimes, they typically do so alone (Zimring, 1998).

Although adolescent risk taking often occurs in groups, it is not known whether the greater prevalence of group risk taking observed among adolescents stems from the fact that adolescents spend more time in peer groups than adults do (Brown, 2004) or from the heightened levels of susceptibility to peer influence that have been shown to characterize adolescence (Steinberg & Silverberg, 1986). In other words, it is not clear whether adolescents simply have more opportunities to engage in group risk taking than do adults or whether, when faced with behavioral decisions in a peer group context, adolescents are more easily swayed toward risky choices.

To our knowledge, only one study has attempted to determine whether there are developmental differences in the effects of actual peer presence on orientation toward risk. In a comparison of adolescents and college students, Hensley (1977) sought to determine whether the tendency for individuals to take more risks in groups than when alone—a phenomenon known as the *risky shift* (Vinokur, 1971)—might differ across age groups. Hensley (1977) used a hypothetical decision-making questionnaire to measure risk acceptance and found that the magnitude of the risky shift was greater among adolescents than it was among college students. However, the study sample was very small (22 college students and 18 adolescents), and these results have not, to our knowledge, been replicated with performance (as opposed to hypothetical) measures of risk taking.

There are other findings that indirectly support the notion that adolescents may be more easily swayed toward risky behavior than adults. Compared with adults, adolescents have limited abilities in areas of psychosocial functioning, such as self-reliance, which likely interfere with the ability to act independently of the influence of others (Cauffman, 1996; Cauffman & Steinberg, 2000; Steinberg & Cauffman, 1996). Not surprisingly, several studies have found a curvilinear relation between age and peer conformity on responses to hypothetical dilemmas about antisocial decision making, with conformity increasing throughout childhood and into midadolescence and decreasing thereafter (Berndt, 1979; Brown, Clasen, & Eicher, 1986; Steinberg & Silverberg, 1986). Although researchers have not examined the developmental pattern of resistance to peer influence beyond late adolescence, there is some evidence that peer influence remains an important predictor of participation in risky behavior even during young adulthood (Andrews, Tildesley, Hopps, & Li, 2002; Horvath & Zuckerman, 1993). Thus, when confronted with risky decisions in the context of a peer group, adolescents, and perhaps even young adults, may be less able than older adults to resist the influence of their risk-prone age mates.

Further support for the idea of heightened peer effects on risky behavior during adolescence comes from additional findings on the risky-shift. Although a number of researchers have found that risk-taking tendencies are greater when individuals are in groups than when alone (e.g., Blascovich & Ginsburg, 1974; Blascovich, Ginsburg, & Howe, 1975; Blascovich, Veach, & Ginsburg, 1973; Kogan & Wallach, 1967; Lamm, 1967; Lamm, Trommsdorff, & Rost-Schaude, 1972; Pruitt & Teger, 1969; Vidmar, 1970; Wallach & Kogan, 1965; Yinon, Jaffe, & Feshbach, 1975), several investigations have found the reverse to be true. Indeed, in some cases, individuals demonstrate a conservative shift and are actually more risk averse when in groups than when alone (e.g., Cohen & Ruis, 1974; Pilkonis & Zanna, 1973; Zaleska, 1974). Accordingly, social psychologists have advanced an alternative theoretical framework for understanding group risk taking. Whereas proponents of the risky shift theory assert that the presence of others should always lead to increased risk taking, advocates for the more recent group polarization theory suggest that the direction of group effects on risk taking depends on the risk-taking tendencies of the group members (Hogg, Turner, & Davidson, 1990). According to this theory, relatively conservative individuals should become even more conservative when grouped together, whereas individuals who are inclined to take risks should make even more risky choices (Hogg et al., 1990). Given this theoretical framework, adolescents' generally greater inclination toward risky behavior as individuals, in combination with their greater susceptibility to peer influence should, in theory, result in a larger effect of peer presence on risky behavior among adolescents than among adults.[1] The goal of the present study is therefore to examine whether adolescents, relative to adults, are more likely to take risks when their peers are present.

The Present Study

In the present study, we examined the differential effects of the presence of peers on risk taking, risk preference, and risky decision making among adolescents (*M* age = 14), youths (*M* age = 19), and adults (*M* age = 37). Our three primary hypotheses were as follows:

Hypothesis 1. Risk taking, risk preference, and risky decision making will decrease with age.

Hypothesis 2. On average, individuals will demonstrate more risk taking, greater risk preference, and more risky decision making when in the company of their peers than when alone.

Hypothesis 3. The difference between levels of risk taking, risk preference, and risky decision making with and without the presence of peers will decrease with age. That is, group effects on risk orientation will be greater among adolescents than among youths, and greater among youths than among adults.

Method

Sample

Our sample included 106 adolescents (54 girls and 52 boys), ages 13 to 16 (*M* age = 14.01, *SD* = 1.02), 105 youths (53 women and 52 men), ages 18 to 22 (*M* age = 18.78, *SD* = 1.07), and 95 adults (48 women and 47 men), ages 24 and older (*M* age = 37.24, *SD* = 12.37). All participants were recruited from areas in and around a major urban center. The adolescents were recruited from middle schools, day camps, and commu-

[1] In keeping with group polarization theory, we are not suggesting that all adolescents should demonstrate shifts toward increased risk taking when in the presence of peers. It is conceivable that some adolescents, when placed in a group with risk-averse peers, might shift toward decreased risk taking. However, we expect that, given generally greater propensities for risk taking among adolescents, adolescents should, on average, be more likely than adults to demonstrate group-induced shifts toward greater risk taking.

nity centers; the youths were recruited from undergraduate introductory psychology courses at a large urban university; and the adults were recruited through fliers posted on urban university and community college campuses, advertisements distributed to community organizations, and word of mouth.

The adolescent sample was composed of 50.9% girls and 49.1% boys; the youth sample was composed of 50.5% women and 49.5% men; and the adult sample was composed of 50.5% women and 49.5% men. These three groups did not differ significantly with respect to gender composition, $\chi^2(2) = .005$, $p = .997$. The three age groups were also very similar in terms of their ethnic composition. The majority of the participants were either White (48.7%) or African American (38.2%). Given the very small percentage of participants from other ethnic groups (the sample included only 1% Native Americans, 7.2% Asian Americans, 3.9% Latinos, and 0.7% others), the three age groups were compared only with respect to the percentages of White versus non-White participants. The adolescent sample included 44.8% White participants and 55.2% non-White participants; the youth sample included 53.3% White participants and 46.7% non-White participants; and the adult sample included 48.4% White participants and 51.6% non-White participants. These three groups did not differ significantly with respect to ethnic composition, $\chi^2(2) = 1.554$, $p = .460$. Finally, on a participant-report parent education rating scale (a proxy for socioeconomic status) where 1 = *less than high school diploma*, 2 = *high school diploma/GED*, 3 = *some college/vocational school*, 4 = *college graduate*, and 5 = *graduate or professional school*, all three age groups reported a mean level of parent education within the range of some college or vocational training. Thus, the three age groups did not differ substantially with respect to gender, ethnicity, or socioeconomic status (as indexed by parent education).

Recruitment and Procedure

Slightly different recruitment procedures were used for the adolescents versus the college students and adults. Each college undergraduate and adult participant was asked to invite to the session 2 people of his or her gender that he or she knew. These groups of 3 were then randomly assigned to a group condition (in which all 3 participants completed the battery of measures at the same time, in the same room, and communicated with each other while completing the tasks and measures) or to a sole participant condition (in which each of the 3 participants completed the battery of measures alone while the other 2 participants waited outside the room where the session took place).

Requirements concerning the need for parental consent among the adolescent participants necessitated a slight modification in this procedure. We found it difficult to get predetermined groups of 3 adolescents to appear for scheduled appointments together and to arrive with all 3 signed parent consent forms in hand. Thus, after first obtaining parental consent from large numbers of adolescents at different recruitment sites, we randomly assigned half of these adolescents within each recruitment site to the group condition (in which they completed the measures with two other teenagers of the same gender from their recruitment site) and half to the sole participant condition (in which they completed the measures alone). Thus, while the adolescent triads in the group condition were always composed of individuals who knew and were familiar with each other (i.e., individuals within each triad were from the same camp, classroom, or community-center summer or afterschool program), they were not necessarily composed of individuals who had selected one another as partners for the experiment. Although the adolescent and two older groups differed in this respect, in the real world, adolescents often find themselves in groups with other teenagers whom they know but have not necessarily selected as companions (i.e., in classrooms, on sports teams, in extracurricular activities, etc.). Moreover, to the extent that friends have been shown to exert more pressure on each other than acquaintances (e.g., McPhee, 1996), the way in which adolescents were recruited resulted in a more conservative test of the hypothesis that, relative to adults, risk orientation among adolescents is more influenced by peer pressure.

Among the adults, 54 participants (27 men and 27 women) were assigned to the group condition, and 41 participants (20 men and 21 women) were assigned to the sole participant condition.[2] Among the youths, 54 participants (27 men and 27 women) were assigned to the group condition, and 51 (25 men and 26 women)[3] were assigned to the sole participant condition. Among the adolescents, 54 participants (27 boys and 27 girls) were assigned to the group condition, and 52 (25 boys and 27 girls) were assigned to the sole participant condition.

All participant triads were composed of individuals of the same gender. However, the ethnic composition of the triads was not constricted in this manner. Among the adults, 37.5% of the triads consisted of all White participants, 43.8% consisted of all non-White participants, and 18.8% of the triads consisted of White and non-White individuals. Among the youths, 45.9% of the triads consisted of all White participants, 37.8% consisted of all non-White participants, and 16.2% consisted of White and non-White participants. Among the adolescents, 19.4% of the triads consisted of all White participants, 25% consisted of all non-White participants, and 55.6% consisted of White and non-White participants.

All participants completed three measures of risk orientation that were part of a battery of measures administered for a larger study of psychosocial development. The entire battery of measures took approximately 1 hr to complete. Each adolescent and adult participant was compensated $20, and each undergraduate participant was given the choice between either a $20 payment or research credit in an introductory psychology course.

Measures

Risk taking. Risk taking was assessed with a video game called "Chicken" (Sheldrick, 2004). Chicken is played on a laptop computer and requires participants to make decisions about whether to stop a car that is moving across the screen once a traffic light turns from green to yellow. The appearance of the yellow light signals the impending appearance of a red traffic light, as well as a potential crash if the car is still moving when the red light appears. Chicken was selected because it measures risk taking in the moment rather than the more deliberative form of risk taking assessed in many studies, in which participants have unlimited time to consider and evaluate all potential decisions and outcomes. Additionally, Chicken requires participants to make actual decisions in a risky situation, rather than simply requiring participants to report what they would do in a hypothetical risky situation.

The game is played from a third-person, side-view perspective (see Figure 1) and consists of 15 trials. In each trial, participants watched an animated car move across the screen for a predetermined amount of time until a yellow traffic light appeared. Before the first trial, players were informed that at some unknown point after the yellow light appeared, the traffic light would turn red and a wall would pop up in front of the car. Players were told that the object of the game was to allow the car to move as far as possible without crashing into the wall. Players controlled whether the car was moving or stopped but not the speed of the car. Participants accumulated more points the further the car moved without crashing but lost any points that had been accumulated on that trial if the

[2] One person was dropped from one of the adult sole participant triads. At the age of 79, we believed this individual to be developmentally dissimilar from the rest of the adult sample.

[3] One person was missing from three of the young adult triads assigned to the sole participant condition. In the first two cases, the 3rd member of the group left before it was his or her turn to complete the session. In the third case, data for the 3rd member of the peer group were excluded because it was later determined that the participant had already completed the study several months prior.

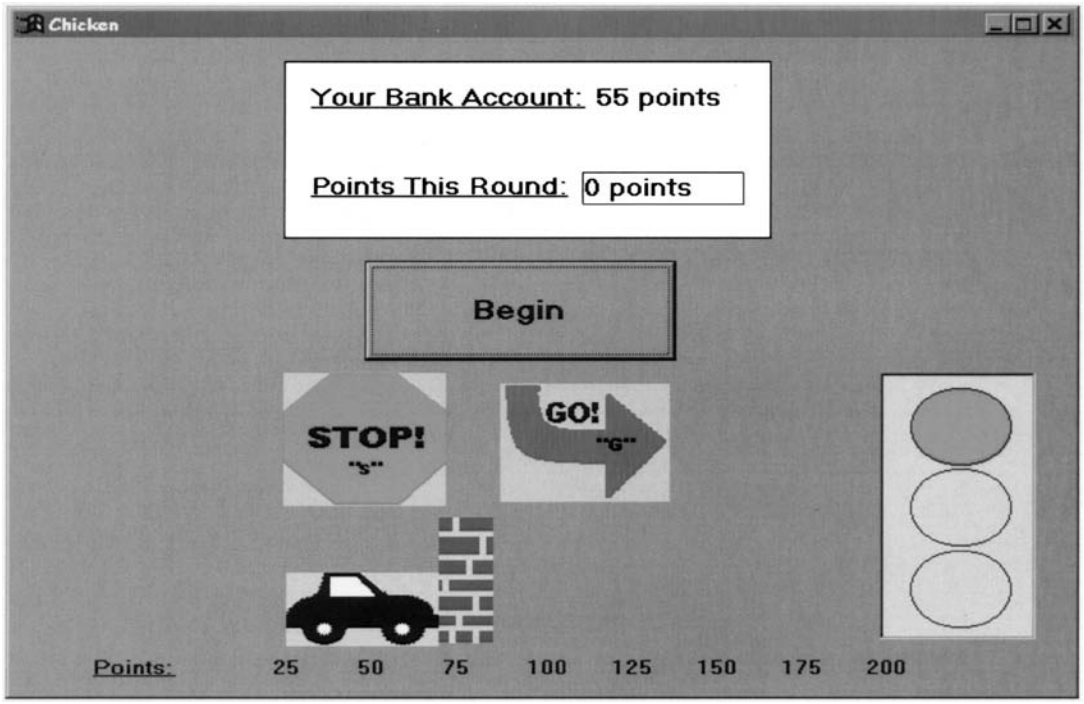

Figure 1. An image from the Chicken video game. In this frame, the traffic light has just turned red. The car was still moving when the light turned red; consequently, a brick wall appeared in front of the car, resulting in a crash.

car crashed. If a player stopped the car before it crashed, the player had the option of restarting the car and allowing it to move further, or leaving the car where it was and accepting the amount of points accumulated. Thus, when the yellow light appeared, players had to decide how much further to allow the car to move, balancing their desire to accumulate points against the possibility of crashing the car into the wall. The latency between the beginning of the trial and the appearance of the yellow light, and between the appearance of the yellow light and the appearance of the wall varied across trials, such that the participants did not know whether the wall would appear suddenly or after some delay. The objectives of the game and the potential positive and negative outcomes (earning points vs. crashing and failing to accumulate points, respectively) were explained to participants during a demonstration. In order to ensure that all participants were equally familiar with the potential consequences of driving through a yellow traffic light, the demonstration round included a depiction of the animated car both driving safely through the yellow light without crashing, as well as driving through the yellow traffic light and crashing into the pop up wall.

The computer recorded the amount of time that the car was in motion between the onset of the yellow light and the car's final stop, as well as the number of car restarts per round. Mean scores for the number of car restarts per round, and the percentage of time the car was in motion were calculated for each participant. Longer moving times and more restarts indicated greater risk taking. Scores on these two indices of risk taking were highly correlated ($r = .61$, $p < 01$) and were therefore standardized and averaged in order to compute a composite indicator of risk taking on the Chicken game.

Participants in the sole participant condition completed the task as described. Participants in the group condition took turns playing the game, but all of them completed 15 trials in a row, as did participants in the sole participant condition. In the group condition, while one participant was playing the game, the other two were told that they could call out advice about whether to allow the car to keep moving or to stop it. The player was instructed that he or she could choose whether to follow the advice of his or her peers.

Risk preference.

A shortened, modified version of the Benthin Risk Perception Measure (BRPM; Benthin, Slovic, & Severson, 1993) was used to assess risk preference. This measure assesses both risk perception (the extent to which one perceives a given activity as carrying the potential for adverse consequences) and risk preference (whether one believes the benefits inherent in an activity outweigh the costs, or vice versa). Only data from the scale reflecting cost–benefit consideration are used in the present analyses. We chose not to include data from the risk perception scale because prior studies have failed to find age differences in performance on this scale (Steinberg, 2004). Similarly, evidence from the research of Beyth-Marom and colleagues (Beyth-Marom, Austin, Fischoff, Palmgren, & Jacobs-Quadrel, 1993) suggests that adolescents and adults are relatively equal in terms of their awareness of the potential for adverse consequences in risky situations. However, as argued by Furby and Beyth-Marom (1992), adolescents and adults may differ in terms of the relative weights or values that they attach to the potential costs and benefits of risky activities. Studies of the relation between risk taking and cost versus benefit consideration suggest that those who give lesser consideration to costs

This document is copyrighted by the American Psychological Association or one of its allied publishers.
This article is intended solely for the personal use of the individual user and is not to be disseminated broadly.

and greater consideration to benefits are more likely to engage in risky behavior (e.g., Fromme, Stroot, & Kaplan, 1993; Goldberg & Fischhoff, 2000; Horvath & Zuckerman, 1993; Lavery, Siegel, Cousins, & Rubovits, 1993; McBride, Weatherby, Inciardi, & Gillespie, 1999; Singer, Dai, Weeks, & Malave, 1998; Thorton, Gibbons, & Gerrard, 2002). Thus, differential consideration or weighting of potential costs versus benefits among adolescents and adults may partially account for observed age differences in risky behavior.

In completing the Risk Preference Scale, participants were presented with five hypothetical scenarios involving risky behavior. These scenarios included having sex without a condom, riding in a car driven by someone who has been drinking, trying a new drug that one does not know anything about, breaking into a store at night and stealing something that one really wants, and driving over 90 mph on the highway at night. They were then asked to rate on a 4-point scale ranging from 1 (*risks are much greater than benefits*) to 4 (*benefits are much greater than risks*) how the risks compared with the benefits of the activity. A mean risk–benefit consideration score was then calculated for each participant by averaging responses across the five scenarios ($\alpha = .68$).

Individuals in the sole participant condition read the scenarios from index cards and indicated their choices on a response card displaying the 4-point scale. Group condition participants followed the same procedure but were told that they could discuss each question. However, they were instructed that they need not reach a consensus and that each could make a final decision at any time. Each participant had his or her own set of response cards and had an unobstructed view of the others' response cards. The administrator recorded individuals' responses.

Risky decision making.

Risky decision making was assessed via the Youth Decision-Making Questionnaire (YDMQ; Ford, Wentzel, Wood, Stevens, & Siesfeld, 1990). Participants were presented with five hypothetical dilemmas, each involving a risky decision. The dilemmas included decisions about allowing friends to bring drugs into one's home, stealing a car, cheating on an exam, shoplifting, and skipping work without an excuse, all of which adolescents, college undergraduates, and adults potentially could have done. Decisions about each dilemma were made within the context of three different scenarios. In the first scenario, participants were informed that no matter what their decision, no negative consequences would result. The second scenario—introduced by Cauffman and Steinberg (2000)—stated that negative consequences might result if the risky course of action were taken. The final scenario stated that negative consequences would definitely occur if the risky course of action were taken.

Only responses from the second decision-making scenario (i.e., negative consequences might result) were included in the analyses for the present study, as this was the only scenario that involved some degree of uncertainty or risk. For each dilemma, participants were asked to decide what they would do "if they were really in that situation" on a 4-point scale that ranged from 1 (*definitely making the risky decision*) to 4 (*definitely not making the risky decision*). Scores were reverse coded, such that higher scores indicated higher risk-taking tendencies. A mean risky decision-making score was calculated for each participant by averaging the scores across the five dilemmas ($\alpha = .65$).

Table 1
Intercorrelations, Means, and Standard Deviations of Study Variables

Variable	1	2	3	4	*M*	*SD*
1. Chronological age	—	−.243**	−.279**	−.091	22.77	11.98
2. Risk taking (Chicken)		—	.147*	.127*	0.00	0.90
3. Risky decision making (YDMQ)			—	.331**	2.01	0.56
4. Risk preference (BRPM)				—	1.50	0.50

Note. YDMQ = Youth Decision-Making Questionnaire; BRPM = Benthin Risk Perception Measure.
* $p < .05$. ** $p < .01$.

The YDMQ was presented on a laptop computer. Individuals in the sole participant condition were asked to indicate their desired choices on cards displaying the 4-point response scale. Participants in the group condition followed the same procedure but were told that they could discuss each situation. They were also informed that they did not need to reach a consensus and that they could each make a final decision at any time. Each group condition participant had his or her own set of response cards, and each had an unobstructed view of the others' cards. The administrator recorded participants' responses. Means, standard deviations, and intercorrelations among the study variables are presented in Table 1.

Results

Data Analyses

Because participants were recruited in groups of 3, scores for participants within each triad could not be treated as independent.[4] In order to accommodate the nested structure of the data, all analyses were performed with the linear mixed model (LMM) procedure in the Statistical Package for Social Sciences 11.5 (SPSS; SPSS, Inc., 2005). Unlike the general linear model (GLM) procedure, which assumes that all observations are independent of one another, the LMM procedure allows for correlated variability among observations. Because the LMM procedure does not permit the simultaneous analysis of multiple dependent variables, separate LMM analyses were performed for each of the three dependent variables (Chicken, BRPM, YDMQ). Prior to entering the independent and dependent variables for each analysis, the structure of the data—individuals nested within triads—was specified. Then, for each analysis, chronological age was entered as a continuous independent variable, and condition (group vs. sole participant)

[4] The adolescent sole participants were not recruited in groups of 3. However, in order to structure the data from the three age groups as similarly as possible, triads of adolescent sole participants were created for purposes of data analyses. The adolescent sole participant sample was subdivided by data collection site and then further subdivided by gender, such that a female from a particular community center could only be grouped with another female from that same community center, or a male from a particular middle school could only be grouped with another male from that same middle school. This was done under the assumption that adolescents of the same gender from the same site would most likely know one another, thus making the triads of adolescent

was entered as a fixed factor. Additionally, gender and ethnicity (White vs. non-White) were entered as fixed variables in order to determine whether these variables moderated age, condition, or Age × Condition effects.

Age differences in risk taking, risk preference, and risky decision making. The effect of chronological age on risk taking and risky decision making was significant, $F(1, 284) = 18.79$, $p < .0001$, $r_{\text{effect size}} = .249$, and, $F(1, 288) = 24.599$, $p < .0001$, $r_{\text{effect size}} = .281$, respectively. During the risk-taking game, younger individuals allowed the car to move forward for longer periods of time after the appearance of the yellow light and were more likely to restart the car after stopping it. Similarly, younger individuals were more likely than older participants to select the risky course of action on the risky decision-making questionnaire. The effect of chronological age on risk preference was not significant, however, $F(1, 288) = .563$, $p = .465$.

Effect of peer presence on risk taking, risk preference, and risky decision making. We found significant effects of peer presence on all three measures of risk orientation. Specifically, compared with those who completed the measures by themselves, participants who completed the same measures with peers present took more risks during the risk-taking game, $F(1, 284) = 15.05$, $p < .0001$, $r_{\text{effect size}} = .224$; gave greater weight to the benefits rather than the costs of risky activities, $F(1, 288) = 3.662$, $p = .057$, $r_{\text{effect size}} = .112$; and were more likely to select risky courses of action in the risky decision-making situations, $F(1, 288) = 6.308$, $p < .05$, $r_{\text{effect size}} = .146$.

Differential effects of peer presence on risk taking, risk preference, and risky decision making as a function of age. The effects of peer presence varied as a function of age on the risk-taking measure, $F(1, 284) = 4.801$, $p < .05$, $r_{\text{effect size}} = .129$, and the risky decision-making measure, $F(1, 288) = 4.943$, $p < .05$, $r_{\text{effect size}} = .130$, but not on the Risk Preference Scale, $F(1, 293) = .284$, $p = .594$. As Figure 2 indicates, for example, the magnitude of the group effect on risk taking was greater among younger rather than older participants (see Table 2 for means and standard deviations). The pattern of results was similar with respect to risky decision making.

The Effects of Gender and Ethnicity

The effects of gender and ethnicity on risk orientation were not focal issues in the present study. Thus, no hypotheses on the effects of these variables were generated. Nonetheless, gender and ethnicity were included in the model in order to determine whether the age, condition, or Age × Condition interaction effects differed across males and females, or between White and non-White individuals.

We found few significant gender effects. There were no differences between males and females on risk taking or risky decision making, nor were there any significant two-way interaction effects involving gender on measures of these constructs. Additionally,

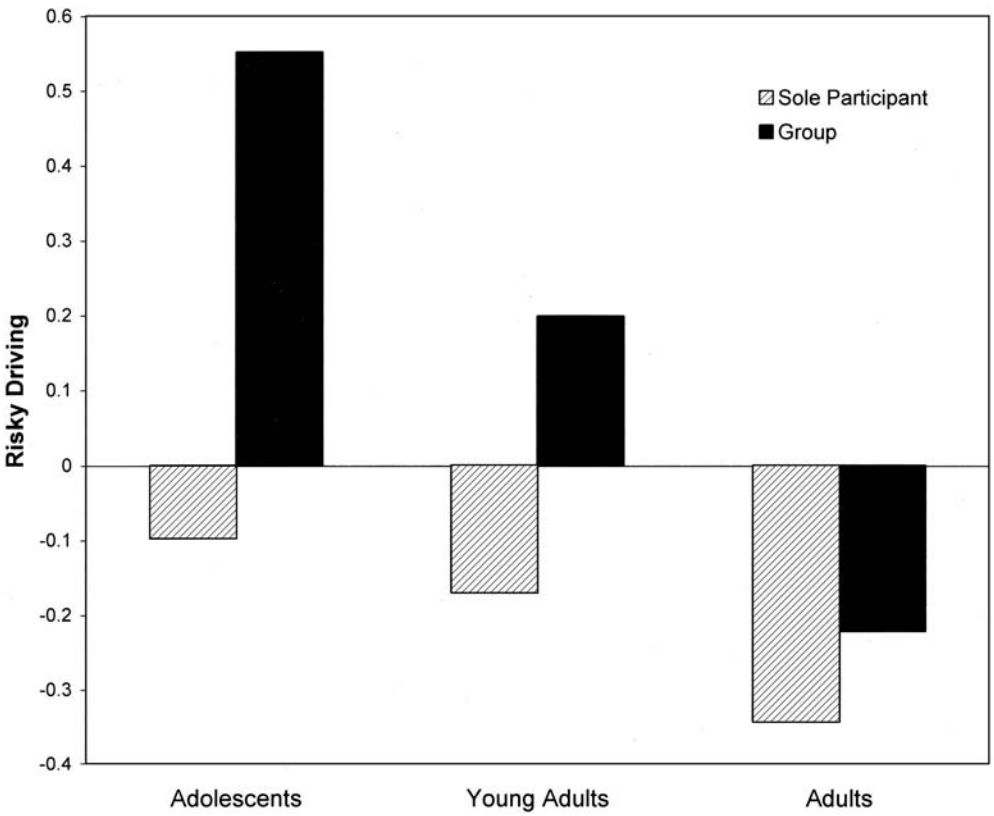

Figure 2. Age × Condition interaction on Chicken game, where higher scores indicate more risk taking.

sole participants as similar to those of undergraduate and adult sole participant triads as possible.

Note. Chicken means are based on standardized scores. YDMQ = Youth Decision-Making Questionnaire; BRPM = Benthin Risk Perception Measure.

we failed to find significant Age × Condition × Gender interactions on any measure of risk orientation. Nevertheless, we did find main effects of gender and gender differences in age and condition effects on the measure of risk preference. First, males gave significantly greater weight to the benefits of risky decisions than did females, $F(1, 288) = 19.961$, $p < .0001$, $r_{\text{effect size}} = .255$. Second, we found that males weighted the benefits of risky activities more heavily when in a group than when alone, but that cost–benefit consideration did not differ substantially between the group and sole participant conditions among females, $F(1, 288) = 6.058$, $p < .05$, $r_{\text{effect size}} = .144$. Finally, we found that among younger individuals, males weighted the benefits of risky decisions more heavily than did females but that among older individuals males and females gave comparable weights to the benefits of risky decisions, $F(1, 288) = 11.089$, $p < .01$, $r_{\text{effect size}} = .193$.

In contrast to these limited gender differences, a number of significant ethnicity effects were identified. First, we found significant differences between White and non-White participants on the measures of risk taking, $F(1, 284) = 11.67$, $p < .01$, $r_{\text{effect size}} = .199$, and risky decision making, $F(1, 288) = 6.645$, $p < .01$, $r_{\text{effect size}} = .150$. However, the direction of these effects differed. Although non-White participants engaged in greater risk taking than did White participants, White participants made more risky decisions than did non-White participants.

Second, the effects of age on risk taking, risky decision making, and risk preference differed across White and non-White individuals, $F(1, 284) = 9.03$, $p < .01$, $r_{\text{effect size}} = .176$; $F(1, 288) = 4.289$, $p < .05$, $r_{\text{effect size}} = .121$; and, $F(1, 288) = 3.922$, $p < .05$, $r_{\text{effect size}} = .116$, respectively (see Table 2). Overall, as noted earlier, adolescents and youths were more oriented toward risk than were adults (although the age effect on risk preference measure did not reach significance). However, within the age groups, risk taking, risk preference, and risky decision making varied somewhat as a function of ethnicity. For instance, although there were negligible differences between White and non-White adults in risk taking and risk preference, among adolescents non-White individuals took more risks and demonstrated a greater preference for risk than did White individuals. Conversely, whereas non-White adults were slightly more likely to make risky decisions than were White adults, White adolescents were slightly more likely to make risky decisions than were non-White adolescents.

Third, White and non-White participants differed in their response to peer presence on the measures of risk taking, $F(1, 284) = 4.383$, $p < .05$, $r_{\text{effect size}} = .123$, and risk preference, $F(1, 288) = 6.517$, $p < .05$, $r_{\text{effect size}} = .149$ (see Table 2). Peer presence was associated with greater risk taking and risk preference among both White and non-White participants. However, condition (group vs. sole participant) differences in mean risk-taking scores were greater among non-White than were those among White participants. On the risk-preference measure, effect sizes for condition differences mirrored this pattern ($r_{\text{effect sizes}} = .203$ and .108 for non-White and White participants, respectively).

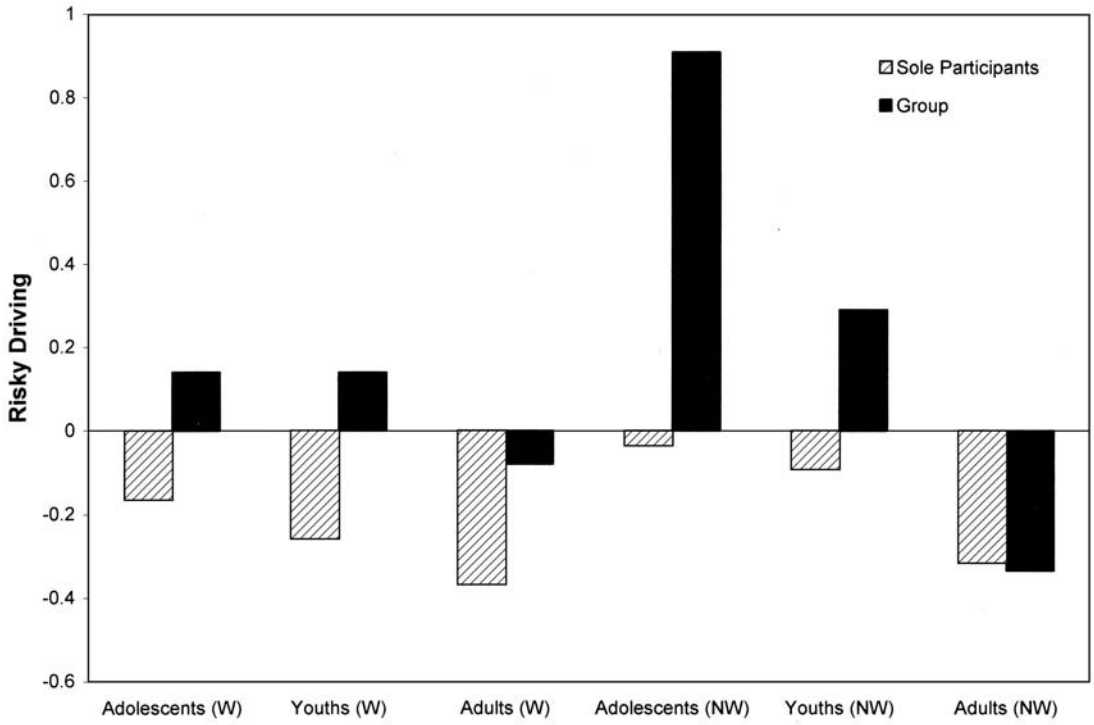

Figure 3. Age × Condition × Ethnicity Interaction on Chicken game, where higher scores indicate more risk taking. W= White participants; NW = non-White participants.

However, effect size estimates indicated the opposite pattern for risk taking ($r_{\text{effect sizes}}$ = .196 and .233 for non-White and White participants, respectively). Effect size estimates are reduced by variability, and although condition differences in mean risk taking were greater among non-White than White participants, scores among non-White participants were more variable (see Table 2 for standard deviations).

Finally, we found significant Age × Condition × Ethnicity interaction effects on risk taking, $F(1, 284) = 4.011$, $p < .05$, $r_{\text{effect size}} = .118$, and risk preference, $F(1, 288) = 5.961$, $p < .05$, $r_{\text{effect size}} = .142$; see Table 2). As noted earlier, peer presence had a greater impact on risk orientation among adolescents and youths than among adults (although the two-way Age × Condition interaction for risk preference did not reach significance). However, the effects of peer presence on the risk-taking and risk-preference tendencies of individuals within some, but not all, of the age groups varied as a function of ethnicity. For instance, among adults, there were no differences between White and non-White participants in the effects of peer presence on risk preference. However, among adolescents, peer effects on risk preference were greater for non-White than for White participants. A similar pattern emerged on the risk-taking measure. That is, peer effects on risk taking were greater among non-White than among White adolescents. However, on this measure, peer effects on adult risk-taking tendencies were greater for White than for non-White participants (see Figure 3).

Discussion

Between adolescence and adulthood there is a significant decline in both risk taking and risky decision making. In addition, our findings suggest that, in some situations, individuals may take more risks, evaluate risky behavior more positively, and make more risky decisions when they are with their peers than when they are by themselves. Most importantly, the effects of peer presence on both risk taking and risky decision making vary as a function of age. That is, although the sample as a whole took more risks and made more risky decisions in groups than when alone, this effect was more pronounced during middle and late adolescence than during adulthood. Thus, relative to adults, adolescents are more susceptible to the influence of their peers in risky situations.

The methodological strengths of this study provide good reason to feel confident about the internal validity of the findings. First, as an experiment that uses random assignment, we were able to control individuals' exposure to peers. Second, whereas the only previous developmental comparison of peer effects on risk taking (Hensley, 1977) relied on a hypothetical decision-making questionnaire and used risk acceptance as a proxy for risk taking, the battery of measures in the present study included not only hypothetical decision-making questionnaires but also a behavioral measure of risk taking that required participants to make actual decisions about how much risk to take in a situation that closely mirrors one faced in everyday life—whether to "run" a yellow light and continue through an intersection. Third, the use of friends, or at least familiar individuals (in the case of the adoles-

This article is intended solely for the personal use of the individual user and is not to be disseminated broadly.

cents), helped to create a more ecologically valid social context than those of many studies of group behavior (e.g., Vidmar, 1970; Wallach & Kogan, 1965; Yinon et al., 1975). Everyday group decision-making situations generally involve friends or acquaintances, and laboratory studies that do not use such groups may not capture the dynamics of real-life group decision making.

It is also necessary to recognize several of the study's limitations. First, although the driving game Chicken is a closer approximation to real-life risk-taking situations than are the typical decision-making questionnaires used in most research of this sort, no laboratory task can adequately simulate real life. No matter how realistic the task, it is difficult to determine whether participants' performance in the laboratory is an accurate representation of their real-world behavior.

Second, different recruitment procedures were used for the adolescents versus the youths and adults. The youths and adults came to the sessions in groups of 3 friends, but the adolescents were assigned to groups of 3 (although all groups of 3 were made up of individuals who were from the same classroom, camp, or community-center program, and who were familiar with one another). Thus, it is conceivable that the older individuals knew one another better than did the adolescents. However, we believe that differences in familiarity among the age groups were minimal and that any effects of peer familiarity of behavior resulted in a more conservative test of our central hypothesis (i.e., that, relative to adults, adolescents should be more easily swayed toward risky behavior by their friends). Although some contradictory findings do exist (e.g., Leary et al., 1994), there is evidence to suggest that the effects of peer familiarity on behavior may either be negligible, or may be stronger when in the company of friends versus acquaintances or strangers. For example, in a study of impression management among young adults, Bohra and Pandey (1984) found very few differences in the attempts of participants to manage the impressions of friends versus strangers. Moreover, in the few cases in which differences were found (e.g., use of other enhancement strategies), interactions with friends were generally more likely to elicit the use of impression management strategies than were interactions with strangers. Similarly, Gardner and Martinko (1988) found that participants in a study of school principals were more likely to use impression management strategies (e.g., other enhancement, apologies) when interacting with more familiar, as opposed to less familiar, individuals. Finally, in a study that examined the relation between familiarity and willingness to exert peer pressure (both antisocial and prosocial) among adolescents, McPhee (1996) found that participants were more likely to exert pressure on friends than on acquaintances. Thus, if differences among the age groups in triad familiarity affected our results in any measurable way, we believe that the adolescent participants, who completed the battery of measures with acquaintances (as opposed to self-selected friends), should have demonstrated group induced shifts toward risk taking that were no greater than those observed among the adults. But, overall, this was not the case.

Finally, it is conceivable that members of the three age groups differed in their prior experience with the subject matter of the risk-orientation measures. Thus, age differences in performance on the risky decision-making and risk-taking measures might be construed as an artifact of differences between the age groups in prior experience. However, any differences in experience with the content of the risky decision-making questionnaire were likely limited to the individual dilemmas. Thus, although a given dilemma might have been relatively more familiar to a particular age group, overall, the items were balanced in such a way that no one age group should have been more familiar with all five dilemmas than any other age group. With respect to the risk-taking measure, Chicken, it is likely that the youths and adults had more first hand experience with driving than the adolescents. However, Chicken is a video game played from a third-person perspective not a driving simulation experienced from a first-person perspective. Although adolescents may have limited experience with driving, they have ample experience with video and computer games Additionally, by adolescence, individuals have spent a great deal of time riding in cars and are surely familiar with the potential consequences of failing to follow traffic signals. Nonetheless, in order to ensure equal familiarity with the potential consequences of running a yellow light, all participants observed a demonstration round prior to playing the game in which they watched the animated car crash after running a yellow light. Thus, we believe that differences in first-hand driving experience had minimal impact on performance.

It is also important to note the few instances in which our hypotheses were not supported. Specifically, we failed to find significant age main effects or two-way Age $\times$ Condition interaction effects on the risk preference measure. In conceptualizing the study, we assumed that those who gave greater weight to the benefits versus the costs of risky decisions should be more likely to take risks. As noted earlier, there are a number of studies that have found strong correlations between cost–benefit consideration and risk taking (e.g., Goldberg & Fischoff, 2000; Horvath & Zuckerman, 1993; Thorton, Gibbons, & Gerrard, 2002). However, the samples in these studies were composed primarily of adults, and there is some evidence to suggest that measures of risk preference may not predict risk taking in the same way among adolescents as among adults. Indeed, despite findings that adolescents are more likely than are adults to engage in risky behavior, several studies suggest that adolescents are relatively similar to adults in their ability to recognize the risks and benefits of their actions. For example, Beyth-Marom et al. (1993) found few differences between adolescents and adults in the spontaneous mention of the costs and benefits associated with several risky actions. This has prompted some to argue that age differences in risky behavior may be better accounted for by differences in psychosocial functioning than by differences in more cognitive aspects of risk orientation, such as risk preference (Cauffman, 1996; Cauffman & Steinberg, 2000; Steinberg & Cauffman, 1996). In this respect, our failure to find age-related differences in individuals' cost–benefit appraisals is not entirely surprising.

We did find some interesting gender differences in risk preference, however. Specifically, males, particularly at younger ages, were more likely than were females to weigh the benefits of risky activities over the costs. Additionally, peer effects on benefit versus cost consideration were greater among males than among females. Although we did not explicitly predict these gender differences, our findings are consistent with several previous studies. For instance, Parsons, Halkitis, Bimbi, and Borkowski (2000) found that, among young adults, males reported more benefits and fewer risks when asked about the consequences of risky behaviors. Additionally, Brown et al. (1986) found that, at least among adolescents, males are more susceptible to peer influence than are females in antisocial or risky situations. Nonetheless, it is inter-

esting that these gender-related differences in risk–benefit consideration did not translate into gender differences on the more direct measures of risk taking or risky decision making.

We also found differences in risk orientation as a function of ethnicity. First, we found differences between White and non-White participants in risk taking, risk preference, and risky decision making—particularly among adolescents (ethnic differences in risk orientation among adults were small to negligible). However, the direction of these ethnic group differences varied across measures. Whereas non-White adolescents demonstrated greater risk taking and risk preference than did White adolescents, White adolescents demonstrated greater risky decision making than did non-White adolescents. This is not entirely surprising given that prior studies have identified differences in the direction of ethnicity effects for different risk behaviors. For example, there is evidence to suggest that minority adolescents (particularly African Americans) are more likely than are White adolescents to engage in risky sexual behavior (e.g., Koniak-Griffin & Brecht, 1995; Neumark-Sztainer et al., 1996; Santelli, Lowry, Brener, & Robin, 2000) and to participate in delinquent activities (e.g., Blum et al., 2000; Hawkins, Laub, & Lauritsen, 1998; Piquero & Buka, 2002). However, there is also evidence to suggest that White adolescents may take more risks than may non-White adolescents when substance use is the behavior of interest. Specifically, a number of studies have found that White adolescents engage in more alcohol and tobacco use than adolescents from many non-White ethnic groups (Best et al., 2001; Blum et al., 2000; Brannock, Schandler, & Oncley, 1990; Douglas & Collins, 1997). Accordingly, researchers studying adolescent risk taking must exercise caution in asserting that ethnic group differences on particular risk measures reflect more general patterns of ethnic group differences in risk taking overall.

Second, we found that peer effects on risk orientation varied across ethnic groups. Specifically, we found that the effects of peer presence on risk preference were greater among non-White than among White participants. Though effect size estimates were not entirely consistent, inspection of mean scores suggests that the same pattern of ethnic group differences may also exist for risk taking. However, if it is, in fact, the case that non-White, relative to White, individuals are more susceptible to peer influence in risky situations, this ethnic group difference appears to be largely limited to adolescence. Although peer effects on risk taking and risk preference were greater among non-White than among White adolescents, non-White adults demonstrated levels of resistance to peer influence that were equal to or greater than those demonstrated by White adults. Though few studies have examined ethnic group differences in the development of resistance to peer influence, there is tentative evidence to support the finding that, relative to White adolescents, non-White adolescents may be more susceptible to the influence of others when in risky situations. For instance, Zimmerman, Sprecher, Langer, & Holloway (1995) found that African American and Hispanic adolescent females were slightly less confident in their ability to refuse unwanted sex than White adolescent females. However, to our knowledge, no prior research has directly examined the possibility that ethnic group differences in susceptibility to peer influence in risky situations may diminish as individuals move into adulthood. Thus, further research is necessary in order to both replicate and explain this finding.

In conclusion, it appears that differences in rates of group risk taking among adolescents versus adults are not simply the product of differences in the amount of time teenagers and adults spend with peers but are instead the result of age differences in individuals' orientation toward risky behavior when in the presence of friends. Moreover, our results suggest that the psychosocial capacities that undergird the ability to resist peer pressure may continue to develop throughout late adolescence and into early adulthood. Thus, interventions aimed at reducing risky behavior among adolescents and young adults—particularly those from ethnic minority groups—ought to focus some attention on increasing individuals' resistance to peer influence. For reasons not yet understood, the presence of peers makes adolescents and youth, but not adults, more likely to take risks and more likely to make risky decisions.

Correction to Gardner and Steinberg (2005)

The article "Peer Influence on Risk Taking, Risk Preference, and Risky Decision Making in Adolescence and Adulthood: An Experimental Study," by Margo Gardner and Laurence Steinberg (*Developmental Psychology*, 2005, Vol. 41, No. 4, pp. 625–635), contains several typographical errors. On p. 630, in the first full paragraph of the first column, the degrees of freedom value that is reported as 293 should instead be 288. Additionally there are several typographical errors in the descriptive statistics table (Table 2). These errors do not have implications for the findings reported in the text of the article, nor do they alter the conclusions drawn from the study. The corrected table appears below.

Table 2
Descriptive Statistics for Group and Sole Participant Conditions by Age Group

		White			Non-White			Total

Previous research on adults has shown that a functional polymorphism in the promoter region of the monoamine oxidase A (*MAOA*) gene moderates the impact of childhood maltreatment on risk for developing antisocial behavior. Thus far, attempts to replicate this finding have been mixed. The current study (i) presents new data investigating this finding in a sample of 975 seven-year-old boys, and (ii) evaluates the extant data by conducting a meta-analysis of published findings. We replicated the original finding by showing that the *MAOA* polymorphism moderates the development of psychopathology after exposure to physical abuse, we extended the finding to childhood closer in time to the maltreatment experience, and we ruled-out the possibility of a spurious finding by accounting for passive and evocative gene–environment correlation. Moreover, meta-analysis demonstrated that across studies, the association between maltreatment and mental health problems is significantly stronger in the group of males with the genotype conferring low vs high *MAOA* activity. These findings provide the strongest evidence to date suggesting that the *MAOA* gene influences vulnerability to environmental stress, and that this biological process can be initiated early in life.

Introduction

Children who experience familial adversity such as physical abuse and inter-parental violence show wide variability in their mental health outcomes.[1,2] Many of these children develop behavioral and emotional difficulties, but many others are resilient and exhibit better functioning than predicted given their exposure to adversity. Recent findings[3] suggest that one explanation for variability in outcomes among maltreated individuals relates to a gene–environment interaction (G × E) involving a functional polymorphism in the promoter region of the monoamine oxidase A (*MAOA*) gene. Specifically, maltreated children with the *MAOA* genotype conferring low levels of the *MAOA* enzyme more often developed conduct disorder, antisocial personality, and violent criminality in adulthood than maltreated children with a high-activity *MAOA* genotype. *MAOA* selectively degrades serotonin, norephinephrine, and dopamine following reuptake from the synaptic cleft, and, therefore, plays a key role in regulating behavior.[4,5] Thus far, efforts to replicate Caspi *et al.*'s[3] results have met with mixed results[6–9] indicating that, as yet, accepting the *MAOA* by maltreatment G × E hypothesis would be premature without further investigation. The present study tested whether Caspi *et al.*[3] original finding would replicate in a representative birth cohort sample of 7-year-old boys.

Previous studies have examined the moderating influence of the *MAOA* polymorphism on psychopathology years after the exposure to adversity. Mental health outcomes as a consequence of childhood adversity have been measured at mean ages ranging from 13 to 26 years.[3,6,7] Whether the moderating effect of *MAOA* activity might be present in early life and closer in time to the stressful experience is unknown, yet this information is crucial for understanding the role that G × E might play in developmental processes. The present study asked whether *MAOA* gene activity moderates the impact of maltreatment on mental health outcomes in childhood.

A downward extension of the G × E hypothesis to young children requires a developmentally informed approach for assessing mental health.[10] Based on evidence from animal[5,11] and human[12,13] studies that linked *MAOA* enzyme deficiency with increased

aggression, Caspi *et al*.'s[3] original G × E investigation of an adult sample targeted antisocial behavior as the hypothesized outcome. Subsequent studies[6–9] using adolescent samples did the same. However, longitudinal data have indicated that adolescent and adult violence and criminality have childhood origins often of the same kind (i.e., antisocial behavior), but also of a different type (e.g., anxiety, hyperactivity).[14] This is because early in development, psychopathology tends to be less differentiated than in later years, when broad behavioral and emotional difficulties develop into more stable and differentiated patterns of maladaptation.[15] Moreover, physical maltreatment is known to elevate risk for a variety of mental health outcomes, including but not limited to antisocial behavior.[16] In childhood, the most common domains of mental health problems include antisocial behavior such as aggression and destructiveness, attention deficits, impulsivity, and hyperactivity, and emotional problems such as anxiety and social withdrawal.[17] More often than not, these domains tend to co-occur in the same child[18] and when they do, this signals greater severity of psychopathology as well as a poorer long-term prognosis.[19] Accordingly, the combination of these mental health problems in 7-year-old boys was the focus of the present investigation.

In order to apply a rigorous test of a G × E, there must be evidence that the risk factor of interest and the outcome are linked via true environmental causation.[10] Otherwise, the association between a putative 'environmental' pathogen and a disorder could be mediated by an unknown third variable, which could reflect unidentified genetic influences. Such a correlation between genetic susceptibility and an environmental risk variable is referred to as a genotype–environment correlation (rGE).[20] The association between familial adversity and mental health outcomes might be explained by rGE of two different kinds.[21] First, aggressive parents may transmit to their children both an adverse rearing environment and a genetic susceptibility toward developing psychopathology (passive rGE). Second, a child with a particular genotype may behave in ways that elicit harsh treatment (evocative rGE). With respect to maltreatment and children's antisocial behavior, evidence of a causal association exists,[22] which argues against rGE as the only mediating mechanism. However, it is desirable to account for possible rGE and so far, only one G × E study involving *MAOA* activity and familial adversity has done so.[6] In the present study, we tested for the presence of passive rGE by controlling for mothers' antisocial personality and evocative rGE by testing whether boys' *MAOA* genotype predicted their exposure to maltreatment.

An extension of the replication strategy is to use meta-analysis systematically to aggregate results over multiple studies, which with regard to this particular G × E hypothesis remains mixed. One possible reason for discrepancy is across-study variability in conceptualizing and measuring the putative environmental risk factor. For instance, in a positive replication by Foley *et al*.,[6] 'family adversity' was measured prospectively as parental neglect, domestic violence, and harsh discipline. In the study by Haberstick *et al*.,[7] a partial failure to replicate, maltreatment was assessed retrospectively using different indicators. Meta-analysis is one tool for ascertaining whether a finding transcends such differences across studies. Meta-analysis is an increasingly valuable method in the field of psychiatric genetics, which in recent years has been plagued by non-replications,[23] leaving questions about gene effects on behavior in doubt. By pooling data from several studies, meta-analysis maximizes power to detect effects and avoids overemphasizing estimates from any single study.[24] The present investigation evaluated the current state of the cumulative evidence regarding *MAOA* activity, childhood adversity, and G × E via a meta-analysis.

Materials and methods

Sample

Participants are members of the Environmental Risk (E-Risk) Longitudinal Twin Study. The E-Risk sampling frame was two consecutive birth cohorts (1994 and 1995) in a birth register of twins born in England and Wales.[25] Of the 15 906 twin pairs born in these 2 years, 71% joined the register. Bias from non-response was corrected as follows.

The E-Risk Study probability sample was drawn using a high-risk stratification sampling procedure. High-risk families were those in which the mother had her first birth when she was 20 years of age or younger. We used this sampling (a) to replace high-risk families who were selectively lost to the register via non-response and (b) to ensure sufficient base rates of children growing up in at-risk environments. Age at first childbearing was used as the risk-stratification variable because it was recorded for virtually all families in the register, it is relatively free of measurement error, and early childbearing is a known risk factor for children's problem behaviors.[26,27] The sampling strategy resulted in a final sample in which one-third of Study mothers (younger only; $N = 314$) constitute a 160% oversample of mothers who were at high risk based on their young age at first birth (15–20 years). The other two-thirds of Study mothers ($N = 802$) accurately represent all mothers in the general population (aged 15–48) in England and Wales in 1994–1995 (estimates derived from the General Household Survey[28]). To provide unbiased statistical estimates that can be generalized to the population of British families with children born in the 1990s, the data reported in this article were corrected with weighting to represent the proportion of young mothers in that population.

The E-Risk Study sought a sample size of 1100 families to allow for attrition in future years of the longitudinal study while retaining statistical power. An initial list of families who had same-sex twins was drawn from the register to target for home visits. Of

the families from the initial list, 1116 (93%) participated in home-visit assessments when the twins were aged 5 years, forming the base sample for the study: 4% of families refused and 3% could not be reached after many attempts. Written informed consent was obtained from mothers. With parent's permission, questionnaires were posted to the children's teachers, and teachers returned questionnaires for 94% of cohort children.

A follow-up home visit was conducted 18–24 months after the children's age-5 assessment. Follow-up data were collected for 98% of the 1116 E-Risk Study families. At this follow-up, teacher questionnaires were obtained for 91% of the 2232 E-Risk Study children (93% of those taking part in the follow-up). The E-Risk Study has received ethical approval from the Maudsley Hospital Ethics Committee.

The present study includes 975 of the 1092 total boys in the E-Risk Study who are of Caucasian ancestry and for whom genotypic data were available. (DNA was not available for 36 boys. These boys did not differ significantly from the rest of the sample on risk for physical abuse exposure or level of mental health problems. Genotyping failure occurred in 23 cases.) Boys' single X chromosome yields two straightforwardly characterized *MAOA* promoter genotypes: high activity (66.3% in this sample) and low activity (33.7%).[3] Girls were excluded because, having two copies of the X chromosome, they fall into two homozygous groups, 'high–high' (39.1% in this sample) and 'low–low' (15.1%), and a third heterozygous group, 'high–low' (45.8%). Based on presently available evidence, girls' status on *MAOA* gene expression cannot be characterized with certainty because of conflicting findings regarding the inactivation status of the *MAOA* locus on the X chromosome.[29,30] In other words, whether the level of *MAOA* transcription in female subjects results from one or both copies of the *MAOA* gene is presently unknown and therefore, inferences about high or low *MAOA* activity in girls cannot be made.

DNA extraction and genotyping

At ages 5 and 7 years, DNA samples were obtained from study members via buccal swabs and extracted using a procedure described by Freeman *et al.*[31] Primer sequences are described by Sabol *et al.*,[4] namely *MAO APT1* (5′-ACAGCCTGACCGTGGA GAAG-3′) and *MAO APB1* (5′-GAACGGACGCTC CATTCGGA-3′). *MAO APT1* was 5′-labeled with the FAM fluorophore. Polymerase chain reaction (PCR) was carried out on a PTC-225 DNA engine (MJ Research, Hercules, CA, USA), using the following cycling conditions: initial 2 min denaturing step at 95°C, followed by 35 cycles of 94°C for 1 min, 55.5°C for 1 min and 72°C for 2 min, and a final extension phase of 72°C for 5 min. Reactions contained 1 × reaction Buffer IV (Abgene, Epsom, UK), 1.5 mM $MgCl_2$, 50 ng of genomic DNA, 5 pmols of each primer, 0.3 mM dNTPs, and 1.5 U of Native *Taq* (Promega, Madison, WI, USA) in a volume of 10 μl. PCR products were denatured in highly deionized formamide and analyzed by electrophoresis on an Applied Biosystems 3100 genetic analyzer (Applied Biosystems, Foster City, CA, USA), set up in genotyping mode, using a POP4 polymer and ROX-labeled GS500 size standard (Applied Biosystems). Results were analyzed using GeneScan v3.7 and Genotyper v3.6 software (Applied Biosystems).

Physical abuse exposure

Children's physical abuse exposure was assessed separately for each twin at the first and follow-up assessments by interviewing mothers with the standardized clinical interview protocol from the *Multi-Site Child Development Project*.[32] The interview protocol was designed to enhance mothers' comfort with reporting valid child maltreatment information, while also meeting researchers' legal and ethical responsibilities for reporting. Under the UK Children Act,[33] our responsibility was to secure intervention if maltreatment was current and ongoing. Such intervention on behalf of E-Risk families was carried out with parental cooperation in all but one case.

The protocol included standardized probe questions such as, 'Do you remember any time when (boy's name) was disciplined severely enough that he may have been hurt?' and 'Did you worry that you or someone else may have harmed or hurt (boy's name)?' Questions were carefully worded to avoid implying that the mother was the perpetrator, so mothers might feel more willing to report that a child had been maltreated. In cases where mothers reported any maltreatment, interviewers probed for details about the incident and recorded notes. Based on the mothers' narrative, interviewers coded if the boy had definitely been physically maltreated ($N = 34$). Examples of such maltreatment included being a victim of adjudicated assault by a teenaged sibling, punished by being burned with matches, had injuries (e.g., fractures or dislocations) from neglectful or abusive parental care, and/or were formally registered with a social services child protection team for physical abuse.

A further 147 boys were designated as 'probable maltreatment.' The 'probable maltreatment' category does not represent a milder form of abuse compared to the 'definite maltreatment' category. Instead, this group includes children who could only be suspected of having experienced maltreatment. In these probable cases, the boy had been reported by concerned schools, neighbors, and/or family members to child protective services but the case was not resolved or registered, he seemed afraid of his father during our home visit, the mother reported that he received frequent physical discipline, or she said he had been smacked harder than intended, leaving a mark or bruise. Some of these boys will not have experienced maltreatment, whereas a subset of them has been maltreated but our coding had to remain uncertain. To enhance certainty, we used information about

intimate partner violence to re-classify children in the probable category who were at greatest likelihood of having been maltreated. Researchers have documented the high correlation between intimate partner violence and child maltreatment.[34,35]

Intimate partner violence in the home was assessed by inquiring about 12 acts of physical violence (e.g., kicking a partner, threatening a partner with a knife) following the protocol of the *Conflict Tactics Scale – Form R*.[36] Mothers were asked about their own violence toward a partner and about any partner's violence toward them in the years of the child's life before the age-5 and the age-7 assessments. A methodological study demonstrated strong reliability and validity for the partner violence scale (i.e., 0.89 internal consistency and 75% inter-partner agreement).[37]

Children in the 'probable' maltreatment category were classified as having physical abuse exposure if their families were in the top 5% of the distribution of partner violence at either the age-5 or age-7 assessments. This method resulted in 28 boys from the 'probable maltreatment' group being added to the group of children we classified for this article as having been exposed to physical abuse. The resulting group totaled 62 boys (6.4% of the cohort unweighted; 4.7% weighted to represent the population) who were exposed to physical abuse.

Children's mental health outcomes

At the age-7 assessment, children's behavior problems were assessed with the *Child Behavior Checklist*[38] and the *Teacher Report Form*,[39] supplemented with items from the Rutter Child Scale[40] and additional items measuring *Diagnostic and Statistical Manual of Mental Disorders, 4th edition*[41] criteria for attention deficit hyperactivity disorder (ADHD). The CBCL cutoff for the clinical range (top 2% of the standardization sample) was exceeded by 7% of E-Risk cohort boys. Symptoms and behaviors were reported for the preceding 6 months and each item was scored as (0) 'not true,' (1) 'somewhat true,' and (2) 'very often true.' Sample items from the *Antisocial Behavior Scale* include 'physically attacks people,' 'lying or cheating,' and 'destroys things that belong to others' ($M = 21.57$, s.d. = 18.02). Sample items from the *Attention Deficit Hyperactivity Scale* include 'very restless,' 'cannot concentrate,' and 'impulsive or acts without thinking' ($M = 16.25$, s.d. = 12.40). Sample items from the *Emotional Problems Scale* include 'too fearful or anxious,' 'unhappy, sad, or depressed,' and 'withdrawn from social interaction' ($M = 11.08$, s.d. = 8.23). Following recommendations from the test manual,[42] we used mother interviews and teacher reports of children's behavior in combination to maximize reliability and validity. Mother and teacher reports of the same behaviors were moderately correlated and alpha reliabilities for all scales exceeded 0.85. Because simple combinatorial rules work as well, or better, than more complicated ones,[43] mothers' and teachers' reports were averaged to create scales of antisocial behavior, attention-deficit hyperactivity, and emotional problems. Principal Components Analysis (PCA) of the three subscales identified a single *Composite Mental Health Problem Scale* that accounted for 64.1% of the variance. Each of the component scales loaded adequately on the factor, with factor loadings ranging from 0.61 to 0.90. All scale scores were standardized with a mean of 0 and a standard deviation of 1.

Maternal antisocial personality symptoms

Mothers reported on their own lifetime antisocial history. Questions were derived from the *Diagnostic Interview Schedule*,[44] supplemented by items from the *Young Adult Behavior Checklist*.[45] The items covered illegal behavior, deceitfulness, impulsivity, aggressiveness, recklessness, and irresponsibility. A symptom was considered to be present if the mother reported behavioral items representing the symptom as being 'very true or often true.' Symptom counts in this study ranged from 0 to 6 ($M = 0.61$, s.d. = 1.07).[46]

Statistical analyses

First, we used ordinary least-squares regression to test the main effect associations of boys' physical abuse exposure and *MAOA* genotype in predicting mental health problems. Second, we tested for an interaction between *MAOA* activity and physical abuse exposure in predicting boys' mental health problems. Third, we tested whether boys' *MAOA* genotype was associated with risk for physical abuse exposure (i.e., evocative rGE). Fourth, we controlled for a possible passive rGE by adjusting for the effect of maternal antisocial personality symptoms in the regression analyses. Analyzing two boys in each family creates dependence in the data, and thus all regression results are based on the sandwich or Huber/White variance estimator,[47] a method available in *STATA 9.0*,[48] which adjusts estimated standard errors to account for that dependence and provides statistical tests that are robust to model assumptions.[49] Fifth, we conducted a meta-analysis pooling results from previous G × E studies of the *MAOA* polymorphism, physical maltreatment, and mental health with findings from the present study.

Results

Allele frequencies

Genotypes in the sample consisted of five variants of the 30-bp repeat sequence: 2- (0.2%), 3- (31.9%), 3.5- (2.1%), 4- (64.2%), and 5-repeats (1.6%). These allele frequencies matched closely the frequencies reported in other Caucasian samples.[31] In terms of expression, all studies agree on the functional classification of the two most common alleles, that is, 3-repeats (low activity), and 4-repeats (high activity). Of rare alleles, both Sabol *et al*.[4] and Deckert *et al*.[50] assayed the 3.5-repeat with the same result (high activity), whereas a discrepancy resulted for the 5-repeat. We chose the classification of Sabol *et al*.[4] (i.e., 5-repeat equals low

activity) as they assayed three cell lines as opposed to one. The rare 2-repeat, of which only two cases exist in our sample, was classified as low activity based upon precedence in previous studies. Dropping the 18 boys with the 2- or 5-repeat alleles did not alter the pattern of findings nor their significance.[3,6,7]

Predicting composite mental health problems

Sample sizes, group means, and effect size comparisons are presented in Table 1. As expected, there was a significant main effect of physical abuse exposure on children's mental health problems (Table 2). In addition, we found a significant main effect of *MAOA* activity ($P=0.017$), such that boys with the high activity allele had a higher level of mental health problems. The test for the interaction between *MAOA* activity and physical abuse exposure revealed a significant G × E ($b=-0.84$, s.e. = 0.40, $t=2.09$, $P=0.037$). This interaction showed that the effect of physical abuse exposure was significantly weaker among boys with high *MAOA* activity ($b=0.61$, s.e. = 0.22, $t=2.83$, $P=0.005$) than among boys with low *MAOA* activity ($b=1.45$, s.e. = 0.33, $t=4.40$, $P<0.001$) (see Figure 1).

Next, we examined whether there might be evidence of a rGE in two ways. First, we tested for the possibility that a child's genotype might be involved in evoking or eliciting physical abuse exposure. We found that it did not. Boys' *MAOA* activity was not significantly associated with likelihood of exposure to physical abuse (low-activity *MAOA* 3.5%; high-activity *MAOA* 5.3%; $F_{(1,974)}=1.89$, $P=0.170$). Second, we tested whether a child's *MAOA* genotype might be related to the likelihood of experiencing physical abuse indirectly via an association with

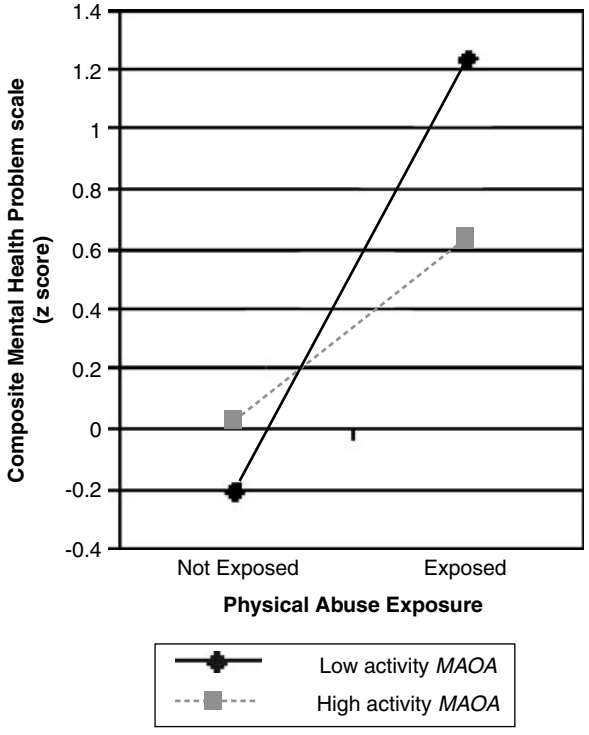

Figure 1 Gene-by-physical abuse exposure interaction predicting children's composite mental health problems.

Table 1 Sample sizes, means, standard deviations, and effect size (Cohen's *d*) comparisons of age-7 mental health outcomes in boys by *MAOA* genotype and physical abuse exposure

Abbreviations: MAOA, monoamine oxidase.

parental characteristics that increase environmental risk exposure. Maternal antisocial personality symptoms were significantly correlated with children's likelihood of physical abuse exposure ($b = 1.22$, s.e. = 0.26, $t = 4.79$, $P < 0.001$). However, when the model was adjusted for the main effects of physical abuse exposure, *MAOA* genotype, and maternal antisocial personality symptoms, the interaction between *MAOA* activity and physical abuse exposure remained significant (Table 2).

Do results hold for component mental health subscales?

We repeated the analyses separately predicting each of the component mental health subscales to examine whether the G × E interaction finding would be robust across multiple outcomes. All subscale findings of the interaction were in the predicted direction (Figure 2a–c) and mirrored the findings reported for the composite mental health measure. However, only the ADHD subscale yielded clear statistical significance ($b = -0.78$, s.e. = 0.35, $t = 2.26$, $P = 0.024$) (Table 2). This G × E finding remained significant ($P = 0.014$) after controlling for maternal antisocial personality symptoms.

Meta-analysis

We included studies in our meta-analysis if they fulfilled four criteria. First, the study had to be published in a peer-reviewed journal. Second, the study had to include genotypic information on the variable number tandem repeat polymorphism in the promoter region of the *MAOA* gene. Third, the study had to include a measure of serious familial adversity in childhood that was significantly associated in a main effect fashion with the outcome measure. Fourth, the sample had to be drawn from a non-clinical population. In addition to the present study, we know of four previous studies that meet all criteria.[3,6–8] A study by Young *et al*.[9] was excluded

[a]*N*s range between 954 and 959 across models because of missing data on boys' mental health measures or maternal antisocial personality symptoms.

Abbreviations: ADHD, attention deficit hyperactivity disorder; MAOA, monoamine oxidase A; rGE, gene–environment correlation.

The table presents final models with main effects and interactions entered simultaneously.

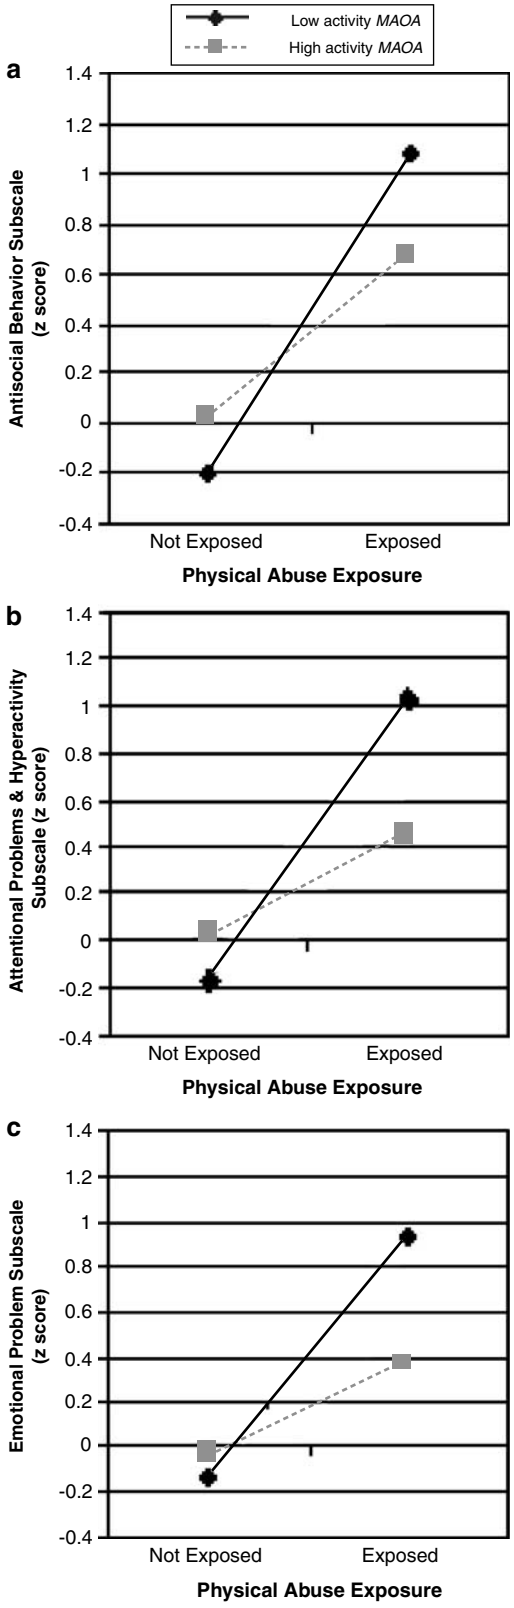

Figure 2 Gene-by-physical abuse exposure interaction predicting subscales of children's (**a**) antisocial behavior, (**b**) attentional problems and hyperactivity, and (**c**) emotional problems.

because their entire sample consisted of adolescents in clinical treatment for serious conduct problems, no matched control group was included, and their measure of lifetime conduct disorder symptoms places the temporal ordering of the risk and outcome variables in question.

Standard methods for effect size conversion were used to translate the results of the different studies into a common metric of correlations.[51,52] The correlations of interest were those reported between family adversity and antisocial behavior within each *MAOA* genotype group. If papers reported more than one outcome measure, we chose the most general measure of antisocial behavior (e.g., composite measures). Where necessary, authors were contacted for additional results in order to calculate effect sizes. All correlations were z-transformed and their standard errors derived.

Heterogeneity across studies was assessed using the χ^2-based Q statistic, as well as the I^2 measure of the percentage of across-study variation attributable to heterogeneity.[53,54] Using meta-analysis programs available in *STATA 9.0*,[48,55] fixed- and random-effects estimates and results were consistent across all analyses; we report only results from the more conservative random-effects model. Meta-analysis of the interaction effect was carried out using the difference in the transformed correlations across the *MAOA* groups within each study.

Figure 3 depicts results of the meta-analysis conducted in two ways. First, panel a presents a forest plot of the correlations between maltreatment and antisocial behavior by *MAOA* activity group for all studies. Within the high-activity *MAOA* group, there was no evidence of significant heterogeneity across studies ($\chi^2_{df=4}=0.79$, $P=0.940$, $I^2=0.0\%$), but there was mild–moderate heterogeneity across studies in the low-activity *MAOA* group as indicated by the I^2 measure ($\chi^2_{df=4}=6.29$, $P=0.179$, $I^2=36.4\%$). The random effects pooled estimates within *MAOA* activity groups were as follows: low *MAOA* activity, 0.32 (95% CI: 0.23, 0.40; $P<0.001$); high *MAOA* activity, 0.12 (95% CI: 0.08, 0.17; $P<0.001$).

Second, panel b presents a forest plot of the meta-analysis of the interaction effect based on the differences in correlations by *MAOA* activity group. No significant heterogeneity was detected across the studies ($\chi^2_{df=4}=3.79$, $P=0.440$, $I^2=0.0$). The pooled random-effects estimate of the change in correlations from the high- to low-activity *MAOA* groups indicated a significant effect of 0.18 (95% CI: 0.10, 0.26; $P<0.001$).

We carried out two additional sensitivity analyses on the meta-analysis results. First, we removed the study by Caspi *et al*.[3] and re-estimated the pooled effects to rule-out potential bias contributed by the first published study of this hypothesis.[24,56] This resulted in a significant but reduced pooled difference in correlations of 0.16 (95% CI: 0.07, 0.25; $P=0.001$). Second, we removed the Nilsson *et al*.[8] study, which reported an effect size larger in

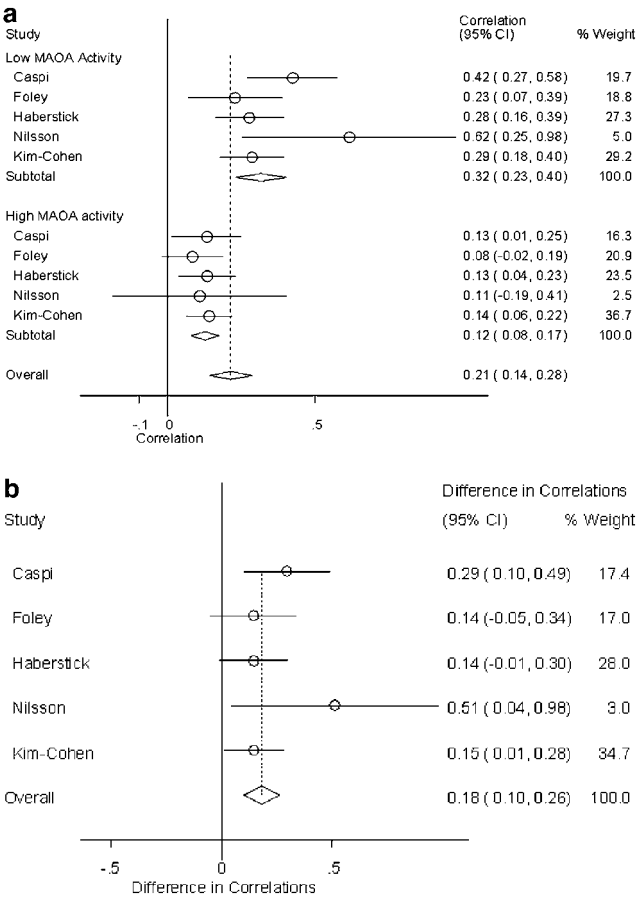

Figure 3 Meta-analysis pooling results across studies. Summary correlations between measures of childhood maltreatment and mental health are presented separately in the low- vs high-activity *MAOA* genotype groups. CI indicates confidence interval. Squares and % weight indicate the size of each study's contribution to the summary correlations indicated by diamonds. (**a**) Forest plot of correlations between childhood maltreatment and mental health, as a function of *MAOA* genotype group in five independent studies. (**b**) Forest plot of the interaction effect based on differences in correlations between childhood maltreatment and mental health observed in low- vs high-activity MAOA genotype groups in five independent studies.

magnitude than the original study by Caspi *et al*.[3] After both studies were removed, results showed a pooled effect of 0.15 (95% CI: 0.05, 0.24; $P=0.002$) (Meta-analysis using effect sizes for children's antisocial behavior from the Kim-Cohen *et al*. study resulted in the same pattern of significant findings. Details are available from first author.).

Discussion

Since 2002 when evidence first appeared that an *MAOA* polymorphism moderates the impact of childhood maltreatment on risk for antisocial behavior,[3] scientists have awaited supporting data through replication. The present investigation evaluated this G × E hypothesis in two ways. First, using data from a representative birth cohort sample of 7-year-old boys, we replicated and extended Caspi *et al*.'s[3] original results. Among children who were exposed to physical maltreatment, boys with the low-activity *MAOA* allele had mental health problem scores that were half a standard deviation higher than boys with the high-activity allele. Second, our preliminary meta-analysis found supportive evidence of this G × E effect. Pooling estimates from five studies, we found that the association between early familial adversity and mental health was significantly stronger in the low-activity *MAOA* vs the high-activity *MAOA* groups. If replication is the '*sine qua non* for accepting a hypothesis' (p. 627),[57] then evidence from the present study brings the field closer toward confirming that *MAOA* activity is meaningfully involved in explaining variability in developmental outcomes as a consequence of maltreatment.

Beyond replication and meta-analysis, this study contributes novel information in several additional ways. First, we extended the findings downward to a sample of 7-year-old boys, indicating that variability in young children's mental health is explained significantly by differences in vulnerability to stress as indexed by a genetic polymorphism. This finding suggests that one mechanism by which maltreatment leads to the development of psychopathology relates specifically to *MAOA* functioning, and that this biological process can be initiated early in life. Eventually, such evidence can inform not only what treatments might help prevent psychopathology in physically maltreated children but also when such intervention might be most successful. Second, we evaluated *MAOA* activity in relation to children's global mental health outcomes in addition to their antisocial behavior. In the Dunedin sample of adult males, the *MAOA* polymorphism did not moderate stress effects in predicting depression,[58] suggesting that in adults, *MAOA* activity moderates the impact of stress specifically towards an antisocial outcome. In childhood, the G × E involving *MAOA* appears to influence ADHD-related symptoms as well as a broader phenotype comprising several domains of mental health that together signal the beginning of a maladaptive trajectory toward the development of adult antisocial behavior. Third, we ruled-out the possibility that the G × E might be explained spuriously by a passive or evocative rGE.

One unexpected finding of the present study was that the *MAOA* polymorphism predicted children's mental health outcomes in a main effect fashion. Boys with the genotype conferring high *MAOA* activity had slightly but significantly elevated levels of global mental health problems as well as antisocial behavior and attention-deficits/hyperactivity relative to boys with the low-activity genotype. This finding is not inconsistent with previously published results of a significant main effect of the high-activity *MAOA* genotype on increasing risk for antisocial behavior and ADHD.[59–61] Moreover, closer inspection of other

G × E studies involving the *MAOA* polymorphism reveals similar findings, albeit at marginally significant levels.[3,6,7] For instance, Foley *et al*.[6] found a nonsignificant trend ($P < 0.14$) for the high-activity *MAOA* allele increasing risk for conduct disorder; after adjusting for the interaction between the *MAOA* polymorphism and maltreatment, the main effect became significant ($P = 0.04$). However, two recent studies found contradictory results with positive prediction from the low-activity *MAOA* genotype to ADHD.[62,63] Further research to resolve these discrepancies is needed to understand the direction of gene effects on conferring risk for psychopathology in the absence or presence of risk exposure.

Strengths of this study include a meta-analysis as well as an original analysis of data from a large, nonselected sample of boys at a young age when early emerging psychopathology predicts continuing difficulties in later life. Genotype, phenotype, and physical abuse exposure were measured using independent methods. The findings, however, should be interpreted in light of several limitations. First, our sample comprised Caucasian twins living in England and Wales. However, allele frequencies for the *MAOA* promoter polymorphism[3,4] and base rates of physical abuse exposure in our sample are comparable to those reported elsewhere.[34] Future research should test whether our findings replicate in singleton children and in non-Caucasian samples. Second, official records of maltreatment history were not available. However, unlike many large-scale studies that rely upon self-complete questionnaires, we interviewed caregivers face-to-face about violence exposure, a method having evidence of good validity.[22] Third, because girls' *MAOA* genotype cannot be characterized with confidence, our findings and the findings of previous studies are informative only about males. More progress toward understanding X-chromosome inactivation and *MAOA* gene expression is needed before the relevance of this finding to female subjects can be evaluated. Fourth, our meta-analysis contained only four studies in addition to Caspi *et al*.'s[3] original study. Therefore, our meta-analysis results should be re-evaluated once further tests of the hypothesis are published.

Ultimately, the goal of genomics research is to prevent mental disorder[57] and to refine treatment strategies.[64] Reliable G × E findings have considerable potential for informing such efforts.[10] However, a statistical interaction between a genotype and an environmental risk factor requires further research to uncover the biological mechanisms involved in the interaction.[65] Because the *MAOA* enzyme selectively metabolizes serotonin, norepinephrine, and dopamine,[4,5] which are involved in multiple brain functions associated with stress regulation,[66] it is likely to be one of myriad factors involved in the development of biological sensitivity to stress and the social context.[67] A statistical G × E involving *MAOA* thus represents an important launching pad for developmental neuroscience research into the underlying causal mechanisms involved in the etiology of psychopathology.[10,64,68–70] Moreover, it is possible that the *MAOA* gene may simply be a marker for a behavioral trait, which itself moderates the association between maltreatment and children's mental health.

Eradicating child maltreatment is clearly the preferred way to combat risk for psychiatric problems, and yet large numbers of children in Western societies are abused and exposed to family violence each year.[35] Once an adverse experience touches off an otherwise 'silent' genetic vulnerability and triggers a cascade of biological events toward atypical development, what can be done to halt or reverse the process? In addition to possible pharmacological interventions, recent research on the serotonin transporter polymorphism suggests that social support can protect even genetically vulnerable children from the negative sequelae of maltreatment.[71] As evidence for significant G × E in predicting mental health continues to emerge,[70] both scientists and the public are becoming increasingly aware that like many developmental processes,[72] the nature of gene effects on behavior, too, is often contingent upon experience.

Acknowledgments

We are grateful to the Study families and teachers for their participation. We thank Robert Plomin and Michael Rutter for their contributions, Thomas Achenbach for kind permission to adapt the CBCL, and members of the E-Risk team for their dedication, insights, and hard work. Terrie E Moffitt is a recipient of a Royal Society-Wolfson Research Merit Award. This research was supported by grants from the National Institute of Mental Health (MH45070 & MH49414), the UK Medical Research Council (G9806489 & G0100527), and the ESRC-SCOPIC Network.
